As Fig. 283 indicates, the bacilli do not disappear from the intestine so quickly, or so completely, as from the blood. There is a lag, which is relatively constant over the early part of the falling frequency curve, but which becomes more pronounced later. A considerable proportion of cases are still excreting *Salm. typhi* in their fæces at a time when positive blood cultures can no longer be obtained; and some cases continue excreting well into convalescence or beyond it.

The results obtained in an extensive series of investigations, at the bedside, on post-mortem material, and by direct experiments on animals, have indicated the probable sequence of events during an attack of enteric fever.

If cultures are taken from various situations during a post-mortem examination, the distribution of typhoid bacilli is usually found to be as follows. In the intestine itself almost pure cultures are frequently obtained from the duodenum and upper part of the jejunum. At lower levels the bacilli become less and less numerous in proportion to the other intestinal bacteria; and, below the ileo-cæcal valve, they may be so outnumbered by *Bact. coli*, and by other organisms, as to escape detection in artificial culture (von Drigalski 1904). Outside the intestine, there are four situations in which *Salm. typhi* is almost constantly present, and from which it can often be isolated in pure culture: the spleen, the enlarged mesenteric glands, the bone marrow, and the gall-bladder. It has been pointed out by Levy and Gaehtgens (1908) that, while the mesenteric glands are always enlarged and cultures from them almost constantly positive, other glands are frequently unaffected. It is of interest to note (Mallory 1898) that the enlargement of the mesenteric lymph nodes is associated with marked proliferation of the endothelial cells of the lymph sinuses, while the lymphoid cells are but little affected.

The intravenous inoculation of typhoid bacilli into rabbits or guinea-pigs is followed by their deposition in the liver, spleen, lymph glands, and bone marrow; but there is, in this case, no selective localization in the mesenteric glands. Lüdke (1909) noted the persistence of typhoid bacilli in the lymphatic glands and bone marrow of the guinea-pig, following intravenous inoculation, and their proliferation in these situations after their disappearance from the blood. Gay (1918) finds that typhoid bacilli persist in the bone marrow of infected rabbits after they have disappeared from the blood, lymph nodes and spleen. Reference to Chapter 47 will afford additional data with regard to the fate of typhoid bacilli after intravenous or intraperitoneal inoculation (Buxton 1907*a*, *b*, Bull 1915).

The presence of typhoid bacilli in the gall-bladder is of particular interest, as will later appear. Von Fütterer (1888) was apparently the first to demonstrate that *Salm. typhi* could be isolated from the gall-bladder in fatal cases of the disease. Gilbert and Girode (1890) confirmed its presence in this organ and Chiari (1894) noted its frequency. Pratt (1901) isolated *Salm. typhi* from the gall-bladder in 21 of 30 fatal cases of typhoid fever, and Scott (1915) from 24 of 28 cases. The evidence for the occasional persistence of typhoid bacilli in the gall-bladder long after convalescence is equally conclusive. Droba (1889) isolated *Salm. typhi* from the gall-bladder contents, and from the interior of the gall-stones removed at operation 17 years after an attack of typhoid fever. Findlay

and Buchanan (1906) isolated the bacillus from the gall-bladder 25 years after an attack, and at the same time demonstrated it in the fæces. In some cases, as in that reported by Dudgeon (1908), *Salm. typhi* has been isolated from the gall-bladder in a case of cholelithiasis, in the absence of any history of typhoid fever. The literature contains many instances of a similar kind (see Ledingham and Arkwright 1912, Gay 1918).

The mechanism by which the gall-bladder becomes infected has been studied experimentally in rabbits. Blachstein (1891) found that bacilli could be isolated from the gall-bladder of these animals for days, or weeks, after an intravenous inoculation of living culture. Richardson (1899) recorded similar observations, and noted that some of the rabbits developed gall-stones, an observation which has been repeatedly confirmed (Gay 1918). The bacilli may reach the gall-bladder very rapidly after intravenous injection, according to Blumenthal (1910) within 10 minutes. They may persist in this situation over long periods (Morgan 1911, Johnston 1912, Gay and Claypole 1913). Weinfurter (1915) records an instance in which they were still present after 9 months.

The most generally accepted view, as regards the route by which the bacilli reach the gall-bladder from the blood, is that they travel from the liver capillaries to the bile canaliculi, and thence down the bile ducts (Doerr 1905, Lemierre and Abrami 1907, Nichols 1916). It has, on the other hand, been stated (Koch 1909, Chiarolanza 1909) that they rapidly reach the gall-bladder even after ligation of the cystic duct, and that nests of bacilli may be found in the capillaries of the gall-bladder wall, suggesting that they pass directly into the viscus by this route. It is probable, as suggested by Gay (1918), that either route may be traversed.

The picture that we have just given of the distribution of typhoid bacilli in the blood, fæces, and tissues is based on results obtained by a technique which, in respect of fæces at least, we know to be considerably inferior to that now at our command. It may well be that the frequency of typhoid bacilli in the intestine during the early stage of the disease has been considerably underestimated. That this is true of paratyphoid B fever, the observations of Glass and Wright (1937) leave no doubt. Using a combination of tetrathionate broth for preliminary enrichment, followed by plating on eosin brilliant green agar, these workers were able, during the investigation of a sharp outbreak of paratyphoid fever at Liverpool, to isolate the bacilli from the fæces of about 83 per cent. of patients in the first week, 94 per cent. in the second, and 88 per cent. in the third. Had more than one specimen of fæces been examined from each patient, the proportion of positive results might have been even higher. Whether the same holds true of typhoid and of paratyphoid A fever is not known; observations on these two diseases by the improved techniques of isolation that have been developed of recent years are badly needed. It is interesting to note that, according to Glass and Wright (1937), paratyphoid B bacilli are not likely to be isolated from the urine during the first six weeks of the disease unless the fæces are also positive; after this time, however, during the so-called "clearance period," the urine is not infrequently positive when the fæces have become negative. Gell and Knox (1942), in their study of the Kettering outbreak of paratyphoid B fever, reached the same conclusion.

Route of Infection.—We have not yet considered the question of the route by which the bacilli gain access to the tissues and the blood stream, during the initial stages of naturally occurring infection. Our knowledge of the epidemiology of enteric fever, and of its mode of spread, makes it quite clear that the bacilli enter the body by the alimentary tract; the point at issue is the situation at which

penetration of the mucosa occurs. It was originally believed that the bacilli passed through the stomach, proliferated in the intestine, and thence invaded the blood stream. This view has been very generally discarded; since it seems clear that the heavy intestinal infection which occurs during the 2nd and 3rd weeks of an attack of typhoid is due, in large part, to the passage of bacilli into the intestine from the gall-bladder, and perhaps from the Peyer's patches and lymphoid follicles. Some authors (Förster 1908) insist that there is no reason to suppose that *Salm. typhi* ever multiplies within the intestinal canal. It has been suggested that the bacilli usually gain access to the tissues *via* the tonsils and lymphoid tissue of the pharynx, rather than through the intestinal wall (Brion and Kayser 1906); and von Drigalski (1904) has reported an epidemic in which 40 per cent. of the cases suffered from an initial faucial angina. In many of these cases he obtained a pure culture of *Salm. typhi* from the tonsils. Whether or not this route may be followed in some cases, there seems no adequate reason for discarding the traditional view that the usual portal of entry to the tissues is through the intestinal lymphatics; and this appears to be supported by the finding that the mesenteric glands are constantly affected.

We have already referred, in Chapter 47, to experiments recorded by Ørskov, Jensen and Kobayashi (1928), who noted the following sequence of events in experimental mouse typhoid, after infection *per os* with *Salm. typhi-murium*: the destruction, in the intestinal tract, of the greater part of the ingested bacteria, as evidenced by a transitory excretion of bacilli followed by a period during which none could be recovered from the fæces: the passage of some bacilli to the mesenteric glands, and their further passage to the blood stream, probably *via* the thoracic duct: a transitory bacteræmia, rapidly brought to an end by the removal of the bacilli by the reticulo-endothelial cells, particularly those of the liver and the spleen: a phase during which active proliferation is proceeding in the liver and spleen, as evidenced by the recovery of increasing numbers of bacilli from these organs, but during which the blood remains sterile: a phase of secondary bacteræmia, associated with a generalization of bacteria throughout the tissues, and a secondary invasion of the intestine, principally *via* the gall-bladder and bile duct.

It seems likely that a similar sequence of events occurs in natural infection in man. If so, it may well be that the incubation period in typhoid fever corresponds to the phases which precede the secondary invasion of the blood stream from the sites of primary proliferation in the liver, spleen and mesenteric glands, the occurrence of this secondary bacteræmia marking the onset of the actual illness. Such a conception receives some support from the occasional isolation of *Salm. typhi* from the fæces and from the blood during the incubation period of the disease.

We have already considered in some detail the course of events during the later stages of the illness, and the factors which determine, in some cases, the persistence of bacilli in the tissues over long periods of time, and their persistent, or intermittent, excretion in the fæces. A few points remain to be discussed. The characteristic lesions in Peyer's patches appear to result from an initial hyperplasia of the endothelial cells in response to the bacterial invasion, followed by necrosis and sloughing, caused in part by the toxic action of some bacterial product, in part by interference with the blood supply. Perforation and hæmorrhage are in the nature of occasional associated accidents. The gall-bladder is one of the most frequent sites of persistent infection; and is, from the epidemiological point of view, the most important, because of the ease with which bacilli escape thence to the intestine, to be excreted in the fæces; but it is by no means the only situation in which the bacilli may remain latent over long periods of

time. Experience with mice (Topley 1926) suggests that the spleen may form a persistent focus of infection; and the well-known typhoid periostitis affords an example of a lesion which may occur long after convalescence from the original illness.

It should be noted that relapses may occur during convalescence, although they are relatively infrequent. They are usually milder and of shorter duration than the original attack; and the mortality is low (Gay 1918). They are undoubtedly due to a re-invasion of the blood stream from the tissues in which typhoid bacilli are still proliferating at the time when the bacteræmic phase of the primary attack is brought to a close. They are milder, and of shorter duration, presumably because specific antibodies are already present, and because the tissues respond promptly to the secondary stimulus.

The Vi Antigen of the Typhoid Bacillus.

It will be convenient at this point to discuss the Vi antigen of the typhoid bacillus, since it will be necessary to refer to it under diagnosis, prophylaxis, and serum treatment of typhoid fever, as well as in relation to the bacteriophage typing of the typhoid bacillus.

Felix and Pitt (1934*a*) found that, when different smooth strains of typhoid bacilli were compared with one another in regard to their sensitiveness to agglutination by an O antiserum, they differed very widely, and that this sensitivity was inversely related to the virulence of the strains as judged by the intraperitoneal injection of mice. Thus three strains that were very slightly agglutinable by an O antiserum killed 10 of 10, 10 of 10 and 8 of 10 mice when injected in a dose of 100×10^6 bacilli; whereas three strains that were freely agglutinable by an O antiserum failed to kill a single mouse when injected in this dose. A high proportion of strains freshly isolated from cases of typhoid fever have been found to be of the mouse-virulent type. In a later paper Felix and Pitt (1934*b*) showed that the virulence of the former strains, and their inagglutinability by an O antiserum, were due to the presence of a special antigenic component, which Felix called the "Vi" antigen.

This antigen, it may be noted, is heat labile; so that agglutination tests to detect its presence or absence must be carried out with living suspensions at a temperature of 37° C. Rabbits immunized with living cultures of highly virulent typhoid bacilli produce, in addition to the usual O antibodies, a Vi antibody which agglutinates the virulent strains; while rabbits immunized with avirulent smooth strains, or with heat-killed virulent smooth strains, produce O antibodies alone. An antiserum prepared against virulent strains may be deprived of its O antibodies by absorption with avirulent bacilli, thus providing a pure anti-Vi serum. A Vi antiserum gives effective passive protection in mice against living virulent typhoid bacilli, while an O antiserum is almost or quite ineffective. An O antiserum will, however, protect mice against the toxic effects of a massive dose of killed typhoid bacilli. These observations have been extended by Felix and his colleagues in a series of subsequent experiments (see Felix, Bhatnagar and Pitt 1934, Felix and Pitt 1935, Bhatnagar 1935, Felix and Bhatnagar 1935).

As mentioned above, the Vi antigen is heat labile; judged by agglutination, it is destroyed by exposure to heat at 60° C. for 30 minutes or 100° C. for 5 minutes. Treatment with 0·5 per cent. phenol likewise destroys it. Formalin in 0·2 per cent. concentration has little immediate effect on its agglutinability, but partly denatures it, so that sera prepared by inoculation of rabbits with a formolized suspension are deficient in their protective and phagocytosis-promoting functions. Alcohol, on the other hand, destroys its agglutinability, but not its power to give rise to potent antibodies in rabbits; in horses,

however, alcohol-treated Vi suspensions call forth only a very small amount of antibody (Felix and Petrie 1938).

The observations of Boivin and Mesrobeanu (1938*a*, *b*, *c*) and of Boivin, Izard, and Sarciron (1939*a*, *b*) have shown that both the O and the Vi antigen of *Salm. typhi* consist of glycolipoids. Both are toxic to mice—the O considerably more so than the Vi. Chemically they differ in that, on acid hydrolysis, the O antigen yields about twice as much reducing sugar as the Vi, whereas the Vi antigen alone is precipitated in aqueous solutions by aluminium, uranyl, and lanthanum salts (see also Chapter 44).

The Diagnosis of Enteric Fever.

So far we have dealt with typhoid fever as the classical example of enteric infections in general. Before discussing the laboratory methods available for diagnosis we must consider briefly the question as to which members of the *Salmonella* group, other than *Salm. typhi*, give rise to a continued fever of the enteric type. In Chapter 30 we have given a summarized description of the species, or types, that fall within this group, including the type of case from which they have been isolated. Here we may confine our attention to those organisms that have been isolated, at least with some frequency, from cases of continued fever. The rôle of the various members of this group in the causation of acute gastro-enteritis (bacterial food poisoning) is considered in Chapter 72.

The organisms that are able, like *Salm. typhi*, to give rise to enteric fever are *Salm. paratyphi A*, *B* and *C* and *Salm. choleræ-suis*, particularly the *kunzendorf* variety. The reader may be reminded that in the older literature *Salm. paratyphi C* was often referred to as Hirschfeld's bacillus or as the Eastern European type of *Salm. paratyphi C* in distinction to *Salm. choleræ-suis* var. *kunzendorf*, which was often known as the Western European type of *Salm. paratyphi C*. In much of the literature the name *Salm. suipestifer* will be found in place of *Salm. paratyphi C* or *Salm. choleræ-suis*. It may be noted that the disease caused by these two species differs from that due to infection with *Salm. typhi* or *Salm. paratyphi A* or *B* in that the typical picture of an enteric infection is often complicated by lesions of a septic or suppurative type, including endocarditis (see Harvey 1937, Goulder *et al.* 1942, Schwabacher, Taylor and White 1943). It may also be noted that infection with *Salm. choleræ-suis* frequently takes the form of an acute gastro-enteritis instead of a continued fever. Among more recently identified species *Salm. enteritidis* var. *chaco*, *Salm. moscow*, and *Salm. bareilly* have been isolated from cases of continued fever.

Several other species within the *Salmonella* group, though usually causing an acute gastro-enteritis, occasionally give rise to a continued fever of the enteric type. This, for instance, is true of *Salm. typhi-murium*, perhaps better known as *Salm. aertrycke*; it is possibly true of *Salm. enteritidis*. The element of doubt is introduced by the fact that *Salm. dublin*, which is a natural pathogen of cattle, is certainly capable of causing a continued fever in man (see Smith and Scott 1930); and, since the differentiation of this variety from *Salm. enteritidis* is of recent date, it is possible that the earlier reports of isolated cases of enteric fever caused by *Salm. enteritidis* may have been instances of infection with the *dublin* species.

For our present purpose we may confine our attention to the five species that are frequently implicated in the causation of enteric fever, noting that, from this point of view, *Salm. choleræ-suis* var. *kunzendorf* appears to occupy a position of relatively minor importance. Another fact of great significance from the point of view of diagnosis is that the frequency distribution of these various *Salmonella* types is very

different in different parts of the world. This point will be elaborated in a later section.

The methods of diagnosis that are available and their relative value at different stages of the disease will be obvious from the time-relations shown in Fig. 283 and from the discussion of these relations in the text.

Cultural Methods in Diagnosis.—It should be emphasized that the actual isolation and identification of the infecting organism is always the method of choice. The organism is present in the blood in a high proportion of cases during the first week of illness and with decreasing frequency in succeeding weeks. It may be found in the fæces at any stage of the disease, and in the urine, especially in the later stages. A positive agglutination reaction may be highly suggestive, but it does not become positive till about the second week of the disease, and does not possess the same diagnostic reliability as isolation of the organism itself. The distinction between typhoid and paratyphoid fever is easy by blood culture early in the disease, but may be difficult and sometimes impossible at a later stage when diagnosis is attempted by means of agglutination tests alone.

At least 10 ml. of blood should be withdrawn with a syringe or similar device from a vein and transferred to a tube containing an anticoagulant, such as citrate, oxalate, or liquoid. On arrival at the laboratory, the blood should be transferred to a flask containing 50–100 ml. of 0·5 per cent. sodium taurocholate broth, or preferably distributed in about 3-ml. quantities into tubes containing 20 ml. of 0·5 per cent. sodium taurocholate broth, tetrathionate broth (Muller 1925), and brilliant green Esbach broth (Ruys 1934). The cultures should be incubated at 37° C. and plated out daily on to some selective medium such as the bismuth sulphite medium of Wilson and Blair (1927, 1931), the brilliant green eosin agar of Teague and Clurman (1916, 1916–17), or the desoxycholate citrate agar of Leifson (1935), and should not be discarded as negative for at least 5 days. If the only material sent to the laboratory is clotted blood, the serum should be pipetted off, and the clot, after being broken up with a sterile rod, transferred to bile salt broth. A surprisingly high proportion of successful isolations may be secured in this way; and in early cases the clot culture may be positive when the agglutination test is negative (see Soman 1932, 1934, Downie and Fairbrother 1934).

If possible, cultures from the fæces, and preferably from the urine also, should be put up at the same time as the blood. According to Glass and Wright (1937), it is rare, in paratyphoid fever at least, to find the causative organism in the urine during the first 6 weeks of the disease unless it is also present in the fæces. After that, the urine may be positive when the fæces are negative. Nevertheless, exceptions do occur (see Report 1941), and it is wise to examine both fæces and urine as a routine at any stage of the disease.

Two or three 10-ml. quantities of urine should be inoculated into liquid enrichment media and plated out after incubation on to the selective media already mentioned under blood culture.

Of late years much attention has been devoted to the isolation of typhoid, paratyphoid and other members of the *Salmonella* group from the fæces. The time-honoured method has consisted in preliminary incubation of the fæces in peptone water containing brilliant green in a final concentration of 1 : 100,000 to 1 : 500,000, followed by plating on to MacConkey's neutral red bile salt lactose agar or Endo's basic fuchsin sulphite lactose agar as a differential medium. The recent introduction of more highly selective media has, however, greatly improved the chances of isolating enteric bacilli from the stools.

Of preliminary enrichment media tetrathionate broth, either as described by Muller (1925) or in the slightly modified form of Schäfer (1935), is excellent, particularly for paratyphoid bacilli. It has the disadvantage of permitting the growth of *Proteus* bacilli—both the *vulgaris* and the *morgani* types—so that it should be used in combination with a plating medium such as brilliant green eosin agar (Teague and Clurman 1916, 1916–17, Meyer and Stickel 1918, Jones 1936) or brilliant green eosin methylene blue agar (Knox, Gell and Pollock 1942), which suppresses these organisms. Alternatively Kauffmann's (1930–31, 1935–36*a*) modification of Muller's medium, containing bile and brilliant green in addition, may be used. The brilliant green helps to check the growth of *Proteus*. A more effective medium for this purpose is said to be Ruys' (1934, 1940) brilliant green broth containing 2 per cent. of Esbach's reagent (1 per cent. picric acid and 2 per cent. citric acid), which is based on the observation of Dimitrijević-Speth (1929) that Esbach's reagent inhibits the swarming of *Proteus* bacilli; but preliminary results suggest that an even better means of suppressing *Proteus* is by the addition of cacotheline or hydroquinone to brilliant green broth as described by Jones and Handley (1945). For general purposes the sodium selenite enrichment medium described by Leifson (1936) (see Hobbs and Allison 1945) is to be strongly recommended.

Among the solid selective media the bismuth sulphite agar of Wilson and Blair (1927, 1931) has proved in the experience of most workers to be pre-eminently suited to the isolation of typhoid bacilli from fæces and sewage. For paratyphoid bacilli it is perhaps less satisfactory. Eosin brilliant green agar, studied by Jones (1936), has likewise proved its worth. Another medium that has been used increasingly of late is Leifson's (1935) desoxycholate citrate medium (see Hynes 1942). The addition of 0·5 per cent. lithium chloride to Endo's medium (Havens and Mayfield 1933) is said to improve its selectivity. In a comparison based on the isolation of 724 strains of typhoid bacilli, Mayfield and Gober (1940) cultured 74 per cent. on lithium chloride Endo, 82 per cent. on desoxycholate citrate, and 83 per cent. on Wilson and Blair's bismuth sulphite agar. In 195 instances the organism was isolated on only one medium, namely 42 on lithium chloride Endo, 65 on desoxycholate citrate, and 88 on bismuth sulphite agar.

It will be realized that if the maximum number of successful isolations is to be obtained, it is advisable to use a combination of one or two enrichment liquid media with two or three selective solid media. According to Hobbs and Allison (1945), the best two liquid enrichment media for general purposes are sodium selenite and tetrathionate, and the best two solid selective media, for plating either directly or from cultures in enrichment media, are Wilson and Blair's bismuth sulphite agar and Leifson's desoxycholate citrate agar.

Great care should be exercised over the collection of specimens of fæces and urine for examination. In hospitals imperfectly sterilized bedpans and urinals afford a frequent source of contamination, and it is much better to provide every patient from whom a specimen is required with a special grease-proof, cardboard container into which the excreta can be passed directly (see Holt, Vaughan and Wright 1942). Alternatively a rectal swab may be taken. The fæces should be examined as fresh as possible; if this is impracticable, they should be collected into the buffered glycerol saline solution described by Sachs (1939) or the desoxycholate citrate solution described by Bangxang and Eliot (1940) to prevent the overgrowth of typhoid-paratyphoid bacilli by coliform organisms. Cultures should be made on to two or three of the selective solid media just mentioned, with and without preliminary enrichment. Non-lactose-fermenting colonies may be tentatively identified by slide agglutination (Report 1939), and confirmed by motility, biochemical and tube agglutination reactions (see Bridges and Taylor 1944). It may be noted that the serum of some rabbits may contain agglutinins to the so-called α antigen, which is found in certain strains of coliform and *Proteus* bacilli. Non-lactose-fermenting colonies, not belonging to the typhoid or paratyphoid groups, may be agglutinated by

the serum of such a rabbit, and may give confusing results (Stamp and Stone 1944). The occurrence of the small colony variant of *Salm. typhi* must be remembered (see Morris *et al.* 1943).

Whatever selective and differential media are employed, the frequency of isolation of typhoid and paratyphoid bacilli will be significantly increased by making repeated platings from the primary enrichment culture. Topley and Fielden (1922) pointed out that, in an ordinary broth culture from a specimen of fæces, various bacterial species succeed one another as the dominant viable organisms, and that it is a relatively common event to obtain a pure culture of *Bact. coli* on a plate seeded after 24 hours, and a pure culture of *Salm. typhi* on a plate seeded after several days' incubation. In a selective medium, on the other hand, typhoid bacilli tend to develop before *Bact. coli*; thus Waldhecker (1935) notes that plating from a tetrathionate brilliant green bile selective medium after 5 hours' and 10 hours' incubation, instead of after 20 hours' only, considerably increased the percentage of positive results (see also Boecker 1935).

It must, in particular, be emphasized that the isolation of typhoid or paratyphoid bacilli from a specimen of fæces depends more on the relative numbers of these bacteria in the particular specimen examined than on any detail of technique. No reliance can be placed on a single negative result, whatever method of examination is employed; and in carriers or convalescents, where the excretion of these organisms may be intermittent, many specimens may have to be examined before a positive result is obtained.

The Agglutination Reaction in Diagnosis.—In applying the agglutination reaction in the diagnosis of enteric infections we must first decide which of the possible causative organisms we shall include in our test. This obviously depends on the actual frequency of the different types of infection in the particular part of the world in which we happen to be working. In Great Britain, for instance, the very great majority of enteric infections are, at the present time, caused by infection with either *Salm. typhi* or with *Salm. paratyphi B*, whereas in British Guiana, *Salm. typhi* and *Salm. paratyphi C* constitute the dominant species (see Giglioli 1930). This problem of the relative frequency of different types of infection also arises in connection with the interpretation of agglutination tests, and will be considered more fully under that head. For the moment we may suppose that we desire to include in our test all the species that usually cause a continued fever of the enteric type, but to exclude those that usually give rise to an acute gastro-enteritis.

This leaves us with *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi B*, *Salm. paratyphi C*, and *Salm. choleræ-suis* var. *kunzendorf*. All these species contain both flagellar and somatic antigens (see Chapter 30), and many observations that have been recorded during recent years have shown quite clearly that the agglutinins acting on both these antigens must be considered.

It has been shown, for instance, that some cases of enteric infection fail to develop H (flagellar) agglutinins while developing O (somatic) agglutinins to relatively high titre (Felix 1924*a*, *b*, 1930, Stuart and Krikorian 1928, Felix and Olitzki 1928, Pijper 1930, Gardner *et al.* 1930, Horgan 1932, Flis and Rosenberg 1934, Bole 1935). A test carried out with formolized broth cultures alone, and thus revealing only H agglutinins, would miss a varying proportion of positive results.

It would appear that the proportion of cases showing O agglutinins only is much higher in some localities than in others. Thus Pijper in South Africa (see Felix and Olitzki 1928) noted 34 persistently negative reactions in 120 cases of undoubted typhoid fever, when

testing for H agglutinins only. Some cases of this type, at least, are infected with O variants of the typhoid bacillus (Olitzki 1928, Gardner *et al.* 1930).

It is equally true that particular samples of serum obtained from typhoid or paratyphoid cases may show flagellar but not somatic agglutinins. Smith (1932) records that 6 of 28 cases of typhoid fever showed H but not O agglutinins when the cases were first examined, while 11 of 42 cases of paratyphoid B fever gave a similar result (see also Downie and Fairbrother 1934, Soman 1934, Flis and Rosenberg 1934, Bole 1935). According to Scott (1941), H agglutinins are seldom absent from the blood of paratyphoid fever cases, though in typhoid fever they may completely fail to appear, or develop late or feebly.

Whether a case ever passes through all its stages developing H but no O agglutinins is as yet uncertain. In any event the lesson is clear—both H and O agglutinins should be searched for in each specimen of blood examined. It must be remembered, however, that occasional cases fail to develop either H, O or Vi agglutinins (Report 1941, 1942*a*).

In selecting suspensions for the serum diagnosis of enteric fever, reference may be made to the Kauffmann-White schema shown on p. 713. There it will be seen that *Salm. typhi* and *Salm. paratyphi A* and *B* all share the common XII somatic antigen. Because of this, and perhaps of other common antigens present in smaller quantity and not represented in the differential diagnostic schema, O agglutinins for paratyphoid bacilli are often demonstrable in typhoid fever, and O agglutinins for typhoid bacilli in paratyphoid fever (Felix 1924*a*, Smith 1932, Cruickshank 1939). It is true that, in persons who have neither been inoculated with T.A.B. vaccine nor suffered previously from any *Salmonella* infection, the O titre for the infecting organism tends to be higher than for the heterologous organism (Gardner and Stubington 1932); but, in general, it is wise to depend for differential purposes on H agglutinins. Even these, as will be seen later, are quite unreliable for distinguishing between the different types of enteric fever, or even for establishing a diagnosis at all, in inoculated persons or in those who have previously been infected with *Salmonella*.

We may note that it is not as a rule necessary to include a Vi suspension, since it is uncommon for Vi antibody to appear in the blood of an active case of enteric fever in the absence of H or O antibody (see Kauffmann 1935), though it may occasionally be useful (Report 1943*a*). The test is said to be of value in prognosis. Bhatnagar (1944), for example, finds that in severe cases of the disease Vi agglutinins are absent, or present in only low titre. On the other hand, cases in which the Vi titre is high—1/50 to 1/250—and is maintained over a number of days, are likely to recover rapidly.

In this country it is usually sufficient in routine practice to test the serum of a suspected patient against the following suspensions: *Salm. typhi* O, *Salm. typhi* H, *Salm. paratyphi B* H, and a composite non-specific *Salmonella* H to detect agglutinins to organisms in the group phase. Rarely it may be necessary to add *Salm. paratyphi C* H, particularly if there is any suspicion of infection with *Salm. choleræ-suis*; though this will usually be detected by the use of the non-specific *Salmonella* suspension. In other countries additional O or H suspensions may be required according to the incidence of various types of enteric fever. To avoid non-specific cross-agglutination the suspensions should be tested before use to ensure their freedom from the so-called X antigen (Topley and Ayrton 1924, Cruickshank 1939). It is always wise to include in a routine test a *Brucella* suspension, since undulant fever may closely simulate typhoid. In cases of con-

tinued pyrexia in which no agglutinins to the organisms already mentioned can be found, the serum should be tested against a suspension of *Leptospira icterohæmorrhagiæ* and of *Proteus OX* 19.

So far we have been considering qualitative results, the mere presence or absence of agglutinins acting on particular antigens; but we actually need to know the concentration in which each of these agglutinins is present in any given specimen of serum.

The results of agglutination tests are commonly expressed as titres, *i.e.*, as the highest dilution of a given serum that will produce agglutination of a given bacterial suspension under specified conditions of time and temperature. We shall, in all cases, wish to determine the real end-point; so that we must specify conditions that will allow this end-point to be obtained. Somatic agglutination, for instance, is slower than flagellar flocculation. Tests with O suspensions should be read after 4 hours' incubation in a water-bath at 50° C., and again overnight. Tests with H suspensions may be read after 2–4 hours under the same conditions. It is usual to employ a geometrical series of dilutions, such as 1 : 20, 1 : 40, 1 : 80, 1 : 160 and so on, and the observed titre is thus subject to a wide margin of error unless some additional precautions are taken. A rough approximation may be made by noting the last tube to show detectable flocculation of the bacilli. By adopting an arbitrary degree of agglutination as a standard, and applying an interpolation table to the actual readings obtained, a much greater degree of accuracy can be attained (see Dreyer and Inman 1917).

But our difficulties do not end here. All suspensions of the same bacterial species are not equally sensitive to agglutination; and if we tested a single sample of serum against a dozen suspensions of *Salm. typhi* prepared from different strains in different ways we might get widely divergent answers. If there were no gross antigenic variations in our strains there would be a limit to such divergence—we should not often find that the titre given by any one suspension was more than, say, two or four times that given by another; but this is a wide margin of technical error.

A valuable lead was given by Dreyer and his colleagues during the first world war (Dreyer, Walker and Gibson 1915, Dreyer and Walker 1916, Dreyer and Inman 1917); and the Standards Laboratory instituted in the Department of Pathology at Oxford under the auspices of the Medical Research Council has since performed an important service in preparing and issuing standard agglutinable suspensions, not only of the flagellated bacilli of the enteric group, but of non-flagellated variants of the same species, and of various other bacteria that are commonly employed in agglutination tests (see Gardner 1920, 1921, 1929). A sensitive suspension of a particular bacterium is adopted as a standard, and any subsequent suspension is compared with this by duplicate testing against an agglutinating serum. The new suspension is then labelled with a number that allows the titre observed with any given serum to be reduced to the titre that would have been observed had the "standard" suspension been employed. Even the use of standard agglutinable suspensions does not ensure uniformity of result. In an international experiment described by Gardner (1937), in which 64 human sera from cases of typhoid or paratyphoid fever were titrated against standard agglutinable suspensions, a surprisingly big variation was recorded between the results of the four different laboratories that took part. Owing to technical errors and differences of one sort and another, and to the bias of individual workers in reading agglutination end-points, it is frankly impossible to expect different laboratories to obtain identical results. This conclusion must always be borne in mind when interpreting titres obtained by other laboratories,

and especially when an attempt is made to over-simplify the problem of serological diagnosis by the establishment of absolute standards.

This brings us to the question as to whether any particular titre, and if so what, can be regarded as a reliable indication of infection with one or other of this group of organisms. The answer is quite definite. *No arbitrary titre can be selected at, or above, which an agglutination can be regarded as "positive" in the diagnostic sense, and below which it can be regarded as "negative". An observed titre for any one of these organisms constitutes one item of evidence which must be considered in relation to all the other evidence available.*

Among the more important ancillary data on which the interpretation of a single agglutination reaction depends are the following:—

(1) The natural level of agglutinins among a random sample of the population in the particular area in which the test is being made.

(2) The stage in the disease at which the sample of blood has been taken.

(3) The state of the patient in regard to previous inoculation with typhoid, or T.A.B., or T.A.B.C. vaccine.

We may discuss these various factors in sequence; but we should note that the average level of agglutinins in a given population, as well as their titre in any particular person, may sometimes be affected by the results of prophylactic immunization.

We shall discuss the available evidence under (1) in some detail, since it has an important bearing on the epidemiology of the disease, as well as on diagnosis. It will be convenient to deal separately with H and O agglutinins and to start with the former.

(1) **Frequency Distribution of Agglutinins in the Population.**—A valuable record of the London population in 1921 is given by Rosher and Fielden (1922), who examined 1,000 samples of serum sent to the laboratory for a Wassermann test, *i.e.*, from patients in whom there was no suspicion of an existing typhoid infection.

These sera were tested against formolized suspensions of *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi B* and certain other members of the *Salmonella* group at dilutions ranging from 1 : 20 to 1 : 640 or more. Since our present knowledge with regard to the diphasic variation of the flagellar antigens was not then available it is impossible to be certain which type of agglutinin was concerned in the flocculation of the diphasic species. Taking the results for the three more important species, with this reservation as regards *Salm. paratyphi B*, we obtain the figures set out in Table 126.

TABLE 126

LONDON

Bacterial Suspension.	Percentage of Sera Agglutinating at 1 : 20 or over.
Salm. typhi	29
Salm. paratyphi A	17
Salm. paratyphi B	23

In 330 instances it was possible to obtain a reliable history as to whether the person had or had not been inoculated. The figures for this sub-sample, again taking the titres of 1 : 20 or over, are set out in Table 127.

TABLE 127

LONDON

Bacterial Suspension.	Inoculated.		Uninoculated.	
	No. of Sera.	Per cent. +	No. of Sera.	Per cent. +
Salm. typhi	149	89	181	3
Salm. paratyphi A	149	58	181	0
Salm. paratyphi B	149	71	181	4

Since many more males than females were inoculated during the war it was to be expected that the figures for the two sexes would differ widely, and this was found to be the case. Thus, among 276 unselected male sera 42 per cent. agglutinated *Salm. typhi* at a titre of 1 : 20; 28 per cent. *Salm. paratyphi A*; and 39 per cent. *Salm. paratyphi B*. Among 165 female sera, 5 per cent. agglutinated *Salm. typhi*; 2 per cent. agglutinated *Salm. paratyphi A*; and 7 per cent. agglutinated *Salm. paratyphi B*.

It is clear that the relatively high proportion of agglutinating sera among the London population as a whole was, in 1921, determined by the presence of a large number of recently inoculated persons.

A similar study was carried out in Manchester a few years later by Smith, Macvie and Newbold (1930); 302 specimens of sera sent to the laboratory for Wassermann tests during the years 1925 and 1926 were tested against formolized suspensions of various bacteria of the *Salmonella* group. In this case type suspensions of the diphasic species were employed, together with a single group suspension to detect the group agglutinins, so that a complete picture of the flagellar agglutinins was obtained over the range of types examined.

Taking first the Manchester population as a whole—and including the results with the type phase of *Salm. paratyphi C*, and the group suspension—the percentages giving agglutination at 1 : 20 or over are set out in Table 128.

TABLE 128

MANCHESTER

Organism.	Percentage of Sera Agglutinating.
Salm. typhi	14·9
Salm. paratyphi A	5·9
Salm. paratyphi B (type)	5·9
Salm. paratyphi C (type)	0·3
"Group" Suspension	6·3

Comparing these figures with those of Rosher and Fielden they show a drop to about a half in the case of *Salm. typhi*, to about a third in the case of *Salm. paratyphi A* and to about a quarter in the case of *Salm. paratyphi B*. Agglutinins for the type phase of *Salm. paratyphi C* appear to be very uncommon in the normal English population. No information was available with regard to the state of inoculation of the persons from whom these blood samples were obtained; but a division into males and females (see Table 129) affords highly suggestive evidence.

TABLE 129

MANCHESTER

Organism.	Percentage of Sera Agglutinating.	
	Males.	Females.
Salm. typhi	23·3	4·7
Salm. paratyphi A	11·6	0
Salm. paratyphi B (type)	9·7	2·0
Salm. paratyphi C (type)	0·0	0·6
"Group" Suspension	7·0	4·7

It will be noted that the figures of Smith, Macvie and Newbold for females agree fairly closely with those of Rosher and Fielden for uninoculated persons of both sexes, or for unselected female sera, so far as *Salm. typhi*, *Salm. paratyphi A* and *Salm. paratyphi B* are concerned. In the case of the latter organism Rosher and Fielden's figure of 4·0 per cent. must be compared with both the paratyphoid B and group figures of Smith, Macvie and Newbold.

The fall in the frequency of flagellar agglutinins among the population as a whole is almost certainly due to a wearing-off of the effect of inoculation. Thus, in the case of *Salm. typhi* Rosher and Fielden found 42 per cent. of agglutinating sera among adult males, compared to the 23·3 per cent. noted by Smith, Macvie and Newbold some six years later.

When we consider titres, as well as the mere presence or absence of agglutinins, the figures provided by Smith, Macvie and Newbold for females (see Table 130) afford a useful guide to the titres we may expect to find in uninoculated adults. The figures under each titre give percentage of sera reacting at that titre, or over. Titres of over 1 : 160 are clearly very exceptional. Below this level there are considerable differences in the frequency of flagellar agglutinins for the different organisms. These conclusions are borne out by the observations of Schwabacher, Ross and Carruthers (1943) made in London and Cambridge about 10 years later.

TABLE 130

MANCHESTER (Females)

Organism.	Percentage of Sera Agglutinating at, or above					
	1:20	1:40	1:80	1:160	1:320	1:640
Salm. typhi	4·7	2·7	0·7	0·7	0	0
Salm. paratyphi A	0	0	0	0	0	0
Salm. paratyphi B (type)	2·0	1·3	0	0	0	0
Salm. paratyphi C (type)	0·6	0·6	0·6	0	0	0
"Group" Suspension	4·7	2·0	1·4	1·4	0·7	0

An extremely interesting contrast to these English figures is afforded by those recorded by Giglioli (1933*a*) for a population of native labourers in British Guiana. Table 131 has been constructed from his data for 350 uninoculated persons, taking the figures for males and females together.

TABLE 131

BRITISH GUIANA (Males and Females)

Organism.	Percentage of Sera Agglutinating at, or above					
	1 : 20	1 : 40	1 : 80	1 : 160	1 : 320	1 : 640
Salm. typhi	24·6	16·0	8·3	4·0	1·7	0
Salm. paratyphi A	9·4	6·9	3·7	1·7	0	0
Salm. paratyphi B (type)	6·0	3·1	2·3	1·1	0	0
Salm. paratyphi C (type)	14·3	11·4	7·1	6·0	2·6	0·6
"Group" Suspension	29·4	20·0	12·9	8·9	2·6	0·9

The figures for H agglutinins acting on *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi C* or the "Group" suspension are all much higher than the corresponding figures for London or Manchester. The discrepancy is greatest in the case of *Salm. paratyphi C*, and this clearly arises from the fact that this type of infection is, as Giglioli (1930) has shown, endemic in British Guiana.

As another contrast we may take the figures given by Alves (1936) for H agglutinins acting on *Salm. typhi*, *Salm. paratyphi A* and *Salm. paratyphi B* among 530 sera from uninoculated natives in Southern Rhodesia. The lowest titre recorded in this series was 1 : 50. At this titre 5·1 per cent. of the sera agglutinated *Salm. typhi*; at 1 : 125 the percentage was 3·8, at 1 : 250 it was 2·2, and at 1 : 500 it was 1·5. No serum agglutinated *Salm. paratyhi A* or *Salm. paratyphi B* in the dilutions tested. Lewin (1934), working in South Africa, records the titres for typhoid H agglutinins among 442 sera from probably uninoculated persons. Of these sera 10·6 per cent. gave agglutination at 1 : 25, 2·9 per cent. at 1 : 100, 1·1 per cent. at 1 : 200, and 0·4 per cent. at 1 : 400—figures which are in near agreement with those of Alves over a similar range.

When we turn to O agglutinins we find our evidence rather less detailed.

So far as figures for this country are concerned, we have combined those recorded by Gardner and Stubington (1932) on 50 normal uninoculated persons in Oxford with those of Beattie and Elliot (1937) on 47 uninoculated students in Edinburgh (Table 132).

TABLE 132

OXFORD AND EDINBURGH. UNINOCULATED PERSONS.

Organism.	No. of Sera Examined.	Percentage Agglutinating at, or above		
		1 : 20 or 1 : 25.	1 : 40 or 1 : 50.	1 : 80 or 1 : 100.
Salm. typhi O	97	26	5	1
Salm. paratyphi A O	50	0	0	0
*Salm. paratyphi B** O	97	22	10	5†

* The suspension employed was prepared from *Salm. typhi-murium*, which normally has the same O antigens as *Salm. paratyphi B*.

† One person had recently suffered from food poisoning.

Very similar results were reported by Schwabacher, Ross and Carruthers (1943), who examined a total of 560 "normal" sera. The end-points varied with the length of incubation and the method of reading, but with one or two exceptions the highest O titres met with against both *Salm. typhi* and *Salm. typhi-murium* were 1 : 80.

TABLE 133

BRITISH GUIANA

Organism.	Percentage of Sera Agglutinating at, or above					
	1 : 20	1 : 40	1 : 80	1 : 160	1 : 320	1 : 640
Salm. typhi O.	16·3	3·7	0·9	0·3	0·3	0
Salm. paratyphi B O. . . .	20·3	5·7	2·0	0·3	0·3	0
Salm. paratyphi C O. . . .	19·4	9·4	3·1	2·0	0·9	0·3

Giglioli (1933*a*) included O agglutinins in his survey among the native labourers in British Guiana (Table 133). It will be noted that the O agglutinins among this sample of the population show no excess, where comparison is possible, over the English figures, in striking contrast to the marked excess shown with H agglutinins.

Horgan (1932) has tested 70 sera from Sudanese with no evidence of enteric infection, and no history of inoculation. At a titre of 1 : 25, 7·1 per cent. agglutinated an O suspension of *Salm. typhi*, 4·3 per cent. agglutinated an O suspension of *Salm. paratyphi B*, while no serum agglutinated an O suspension of *Salm. paratyphi A*.

Lewin (1934) gives the following percentages for typhoid O agglutination at various titres among the 442 sera examined by him: 45·0 per cent. agglutinated at 1 : 25, 4·5 per cent. at 1 : 100, 2·0 per cent. at 1 : 200, and 1·8 per cent. at 1 : 400.

Alves (1936) gives figures for typhoid O agglutinins among 300 sera from normal uninoculated natives in Southern Rhodesia: 9·33 per cent. gave agglutination at 1 : 50, 2·67 per cent. at 1 : 100, 2 per cent. at 1 : 250 and 1 per cent. at 1 : 500.

Where comparison is possible these figures are not widely discrepant; and they suggest that the frequency and concentration of O agglutinins in different parts of the world differ much less than the frequency and concentration of H agglutinins. This is not surprising in view of the fact that the antibody response to specific stimulation with the O antigens is known to be more transitory than the response to the H antigens. There are some reasons for believing that the normal O agglutinins, when present to low titre only, represent normal antibodies of the type that have not arisen in response to infection (see Chapter 49).

Further surveys of this type are badly needed. We should have an accurate knowledge of the level of H and O agglutinins among the normal population in all those parts of the world in which the laboratory diagnosis of enteric infections is undertaken. Moreover, these surveys should be carried out by a standardized technique, and with standard reagents. The figures quoted above are not, indeed, strictly comparable with one another because these requirements were not always fulfilled.

(2) Stage of the Disease.—The next factor that we have to consider in a diagnostic agglutination test is the stage of the disease at which the sample of blood was taken.

Reference to Fig. 283, p. 1520 and to Figs. 260, 261, p. 1121, will indicate that the significance of a positive or negative agglutination test, or of a positive result to any given titre, varies according to the stage of the disease at which the sample of blood was taken.

It is clear that little importance can be attached to a negative agglutination test on a sample of blood taken during the first week of illness. It does *not* follow that a test made at this time is useless. It is often of the greatest value since, taken in conjunction with tests made at a later period, it often enables us to demonstrate that a significant rise in agglutinins has occurred; the demonstration of such a rise has far more diagnostic significance than the demonstration that any particular sample of serum gives agglutination to a particular titre, unless that titre is a very high one.

As an illustrative example, bearing in mind our evidence with regard to the distribution of normal agglutinins, let us suppose that we find that a sample of serum, taken from a patient in the first week of the disease, gives an H titre of 1 : 20 against the typhoid bacillus. If the sample had been taken in British Guiana, this finding would have almost no significance, since about 1 normal person in 5 would give this titre. If it had been taken in South Africa, it would have been more suggestive. If it had been taken in England it would have been still more suggestive; only about 1 normal person in 20 would give this titre. If we found, in addition, an O titre of 1 : 50, the significance of the H titre of 1 : 20 would be greatly increased. Similarly, a 1 : 20 H titre against *Salm. paratyphi C* in England would be very suggestive of infection. In British Guiana it would have almost no significance.

If, however, we found these titres in a specimen of serum taken from a patient towards the end of the second week of the disease, or in the beginning of the third, their significance would be entirely altered. By that time a patient has usually developed an H titre well above 1 : 20, and an O titre well above 1 : 50. If we found such low titres at so late a period we should be inclined to suspect that they were due to some cause other than active infection.

Clearly we should like to have figures for the average H and O titres against the causative organism at each period of infection, and for each type of enteric infection; but we have to be satisfied with something much less than this, because records that afford all the necessary data are by no means plentiful. Such figures as we have, however, give us a very useful lead.

Gardner and Stubington (1932) in 40 cases of typhoid fever record H titres of which all but 3 were above 1 : 125, 30 were 1 : 250 or over, and 14 were 1 : 1,000 or over. Of the O titres all were over 1 : 125, 37 were over 1 : 250, and 13 were over 1 : 1,000. In 40 cases of enteric fever caused by *Salm. paratyphi B* the level of H agglutinins tended to be rather higher, but the level of O agglutinins, either for *Salm. typhi* or *Salm. paratyphi B*, definitely lower. Twenty-two of the 40 sera showed an O typhoid titre of less than 1 : 125, and 17 showed an anti-paratyphoid B O titre below this limit. Somewhat similar results are recorded in several of the papers referred to above, and in others not quoted.

In most instances it is not possible from the records to determine the day of disease on which the different specimens were taken; but it seems a fair conclusion from the data that the great majority of typhoid infections will, during the 3rd week of the disease, show an H titre well over 1 : 100, and usually over 1 : 200, and an O titre of 1 : 100 or over. With paratyphoid infections the H titre against the causative organism will tend to be at least as high as that observed in typhoid fever, but the O titre, particularly if an O typhoid suspension is employed, may be somewhat lower.

(3) Effect of Previous Inoculation.—Let us now turn to the third factor that may influence the interpretation of our results, the effect of previous inoculation with a typhoid, or T.A.B. vaccine. This factor is particularly important in the

diagnosis of enteric infections among troops in war-time, or in countries where the risk of enteric infection is so high that many of the white or native population are inoculated.

Considerable assistance is gained, in the solution of this technical difficulty, by the difference in the nature of the antibody response to the H and O antigens. Felix (see above), who first emphasized the value of this method, originally stated that O agglutinins were not formed in response to antityphoid inoculation, and that hence O agglutination had the same diagnostic value in the inoculated as in the uninoculated. This, however, is not the case.

Thus Gardner (1929) found that of 6 persons with a history of inoculation in past years 1 gave O agglutination with *Salm. typhi* at a titre of over 1 : 200 and of 11 persons inoculated 4 weeks before testing 3 gave titres of this order. To check these findings a healthy adult, who had been inoculated some 14 years earlier, was given 2 inoculations of T.A.B. vaccine and his agglutinins were determined at frequent intervals during the following month. The flagellar agglutinins were raised from a titre of 1 : 185 to a titre of 1 : 1,500; the O agglutinins were raised from zero to 1 : 50; both thereafter sank.

Mudd (1932) showed that sera collected 10 days after the third injection of a T.A.B. vaccine contained O agglutinins to a significantly higher titre (1 : 80 to 1 : 320) than the average normal uninoculated controls; and Horgan (1932) and Giglioli (1933*b*) record similar results.

As compared with these O titres, however, the H titres developed after typhoid and paratyphoid inoculation are very high. They usually attain a level of 1 : 500 or more, and often well over 1 : 1,000. What is much more important the O agglutinins disappear from the circulation far more rapidly than the H agglutinins.

Smith (1932) examined the sera of 17 normal persons who had been injected with typhoid vaccine between the years 1915 to 1929. All 17 showed flagellar agglutinins for *Salm. typhi* at titres varying from 1 : 50 to 1 : 200; two of them showed O agglutinins, one at a titre of 1 : 50, the other at a titre of 1 : 200. Wyllie (1932) examined the sera of 22 persons who had received prophylactic injections of typhoid vaccine between 1928 and 1931; 13 showed no O agglutinins at 1 : 25, 9 reacted at or above this titre, the highest titre reached being 1 : 100 (see also Giglioli 1933*b* and others).

A valuable series of observations on men of the Royal Air Force, illustrating the high and more persistent titres of H agglutinins and the low and more transitory titres of O agglutinins after inoculation, is recorded by Downie and his colleagues (Report 1942*c*). Many of the men had had several injections of T.A.B. vaccine during the previous three years, but the results were classified according to the time that had elapsed since the last injection (Table 134).

It will be seen that the O agglutinin response to *Salm. typhi* was very slight, never reaching 1 : 200, even in those who had received their last injection within three months of testing; but that the H agglutinin response for all three organisms was much higher, in some instances reaching or exceeding a titre of 1 : 1,600 for the two paratyphoid suspensions one to three years after inoculation. Similar results on inoculated naval ratings have been recorded by Beattie and Elliot (1937). The O titres recorded by these observers are a little higher than those reported by Downie, but this was probably due to a difference in reading of the end-point, Beattie and Elliot apparently using the standard agglutination end-point recommended by the Oxford Standards Laboratory and Downie using the +++ agglutination end-point recommended by Felix. (See also J. F. Wilson 1945.)

TABLE 134

There are, then, good grounds for Felix's contention that O agglutinins are of more significance than H agglutinins in the diagnosis of enteric fever in inoculated persons.

There is another way in which this problem has been attacked. By taking several samples of blood from the same patient at different stages of the disease we may construct an "agglutinin curve" and base our diagnosis on fluctuations in titre rather than on the titre obtained with any one sample (see Dreyer, Walker and Gibson 1915, Dreyer and Walker 1916, Dreyer and Inman 1917, Perry 1918, Topley, Platts and Imrie 1920). When an inoculated person becomes infected, the response to infection is superimposed on the residual effect of the earlier response to inoculation, and we get the usual "infection" curve, starting not from zero, but from a base line representing the residual "inoculation" agglutinins. Since the rise in titre is more rapid than the fall, the most useful information will be obtained by repeated tests carried out during the first 3 weeks of infection; but the early part of the fall from the maximal titre attained is usually steep enough to show a significant drop in titre during the early weeks of convalescence.

Experience of this method has shown that, though relatively large fluctuations in the titre of O agglutinins are very suggestive, the same diagnostic significance cannot be attributed to changes in the titre of H agglutinins. Many years ago, Felix (1924*b*) reached the conclusion that H agglutinins were so liable to non-specific stimulation in inoculated persons who contracted a febrile infection that they could not be relied upon to indicate the presence of a specific infection with the typhoid or paratyphoid bacillus. Though it is clear from the observations of Perry (1918) and Topley, Platts and Imrie (1920) that inoculated persons may suffer from febrile infections of many kinds without showing any detectable fluctuations in the titre of flagellar agglutinins, experience has shown that in some persons

a very considerable rise in the titre of these agglutinins may occur during the course of non-enteric pyrexial infection, and that little weight can therefore be attached to such a rise in reaching a diagnosis of the disease.

Summarizing, we may repeat once more that no arbitrary titre of H or O agglutinins can be accepted as diagnostic of active infection. Subject, however, to the conditions and limitations discussed in the previous few pages, we may say that in this country a titre of 1/50 for H agglutinins or of 1/100 for O agglutinins, observed during the first ten days of the disease in a patient who has no history of inoculation or of previous enteric infection, may be regarded as strong presumptive evidence of infection with organisms of the typhoid or paratyphoid group.

In *inoculated* persons or in persons with a previous history of enteric infection, no attention can be paid to H agglutinins; even a considerable rise in titre is of little or no diagnostic importance, since this may be due to non-specific causes. On the other hand, O agglutinins, if present in a titre of 1/100 or over, six months or more after inoculation, are strongly suggestive of active infection, particularly if on re-examination they are found to have altered in titre. Many cases, however, of enteric fever may run their course without ever reaching or exceeding such a titre, thus rendering it impossible to arrive at a diagnosis by serological methods alone. In the rare cases in which both H and O agglutinins are absent from the blood throughout the disease, the Vi agglutination test may prove helpful (see Report 1943*a*).

The Epidemiology of Enteric Fever.

It would take us altogether beyond the scope of this book to discuss in any detail the extensive literature bearing on the epidemiology of enteric fever. It will, however, be useful to summarize the conclusions to be drawn from the available evidence, quoting certain illustrative records and reports, many of which must, of necessity, be arbitrarily selected from the numerous examples available.

The main conclusions which emerge quite clearly from the mass of evidence on record are that the single important source of enteric infection consists in typhoid or paratyphoid bacilli which are living, or proliferating, within the bodies of infected persons; and that the whole problem of prevention, neglecting for the moment the possibility of active immunization, consists in stopping the various routes by which the bacilli may pass from the intestine of one individual to the mouth of another.

Moreover, the evidence obtained during surveys of H agglutinins among the normal population in different parts of the world, where different types of enteric infection are endemic, shows quite clearly that in this, as in other diseases, the frequency of infection is far greater than the frequency of the clinical disease, so that infection from carriers and ambulant cases is almost certainly more important in its total effect than infection from clinically recognized cases (see Chapter 56 and discussion below).

Beyond this point the epidemiology of enteric fever cannot profitably be considered as a whole. Though the original source of infection is the human intestinal or urinary tract, the route of epidemic spread differs notably in typhoid and in paratyphoid fever. The evidence in favour of this conclusion has been carefully marshalled by Savage (1942), whose study affords an admirable example of the inductive method of arriving at broad generalizations by the analysis of numerous

diverse observations. Speaking broadly, it may be said that typhoid fever can probably be caused by the ingestion of relatively small numbers of bacilli, whereas paratyphoid fever does not usually result unless large numbers of bacilli are ingested. It is probably for this reason that, though both diseases may be carried by food, typhoid fever is often borne by water and shell fish, whereas these vehicles are rare in the genesis of paratyphoid outbreaks.

The part played by *water* in the spread of typhoid fever was first established by the painstaking observations of William Budd (1856, 1873) in this country, and has been confirmed by experience in many parts of the globe.

Several classical examples of water-borne outbreaks are on record, such as those at Caterham in 1879, at Worthing in 1893, at Maidstone in 1897, at Lincoln in 1905, at Bolton-upon-Dearne in 1921, and at Malton in 1932 (see Greenwood 1935, Forbes 1938). More recently the Croydon outbreak of 1937 may be mentioned, in which there was a total of 310 cases with 43 deaths (Report 1937; see also Holden 1939). In the United States Gorman and Wolman (1939) were able to collect records of 399 outbreaks of typhoid fever between 1920 and 1936, comprising a total of 12,585 cases, of which 862 proved fatal. The corresponding figures for Canada during the same period were 71 outbreaks, 3,437 cases, and 192 deaths.

Among the most frequent causes of contamination of water are cross-connexion of a main with a polluted water supply, seepage of surface water or sewage into a gravity conduit, surface contamination of shallow wells, and inadequate filtration or chlorination (Gorman and Wolman 1939). It may be noted that the evidence inculpating a particular water supply is almost always circumstantial; partly because the isolation of typhoid bacilli from water is beset with technical difficulties, and partly because the effective pollution is often temporary or intermittent, and has usually ceased by the time the water supply falls under suspicion. The evidence is, none the less, convincing enough. Water-borne outbreaks are generally characterized by a typically explosive onset; the curve of notifications rises suddenly and steeply, the majority of the cases developing within a relatively few days. The curve for the whole epidemic is often characteristically skew, the primary cases due to direct infection from the water supply being followed by secondary crops of contact cases. Less often, particularly when infection of the water is slight and intermittent, instead of an explosive outburst, there is a series of scattered or "dropping" cases or small groups of cases occurring over a considerable period of time, and affecting only a small proportion of the consumers. Suspicion of the water should always arise if building operations have been proceeding on a gathering ground, or if extensions, repairs or other alterations have been going on in the supply services. The infrequency of water-borne outbreaks of paratyphoid fever has already been noted. One small but clear-cut outbreak in the little village of Brixworth in Northamptonshire, in which a shallow well water was found to be heavily contaminated with paratyphoid B bacilli, was described by Jones, Gell and Knox (1942); and Savage (1942) gives references to two or three other outbreaks suspected of being water-borne. Franklin and Halliday (1937) mention one small outbreak in Maryland of paratyphoid A fever in which a common well was exposed to infection by a person convalescent from the disease. In view of the known survival of paratyphoid bacilli in sewage and the not infrequent access that these organisms must gain to water supplies, their failure, in contrast to typhoid bacilli, to set up disease is most striking.

Shell fish, particularly oysters, are another important source of infection in

typhoid fever, though rarely incriminated in paratyphoid fever. They are often bred or fattened in the sewage-polluted waters of tidal estuaries, and they are usually consumed uncooked. Numerous epidemics are on record which can be traced to this source (see Gay 1918), and sporadic cases are likewise common. In France alone Belin (1934) estimated that during the previous fifteen years more than 100,000 cases of typhoid fever had occurred due to the consumption of shell fish, of which 25,000 had ended fatally. The relation between the consumption of shell fish and the incidence of typhoid fever in a large city has been considered in some detail by Niven (1910) in a study of the seasonal prevalence of typhoid fever in Manchester.

Milk follows close on water as an important source of sudden and massive herd infection. Ballard, in pre-bacteriological days, adduced good circumstantial evidence for inculpating a polluted milk supply in a localized epidemic at Islington. Schüder (1901), who studied the records of 640 epidemics, attributed 110 to contaminated milk.

In this country there are numerous records of milk-borne outbreaks of typhoid and paratyphoid fever, of which the 1931 outbreak of paratyphoid fever at Epping affecting 260 persons and causing 8 deaths (Bullough 1931), and the 1936 outbreak of typhoid fever at Bournemouth, Poole and Christchurch affecting at least 718 persons and causing about 70 deaths (Shaw 1937), are among the more important of recent years. In the United States Borman, West and Mickle (1935) were able to collect records of 574 milk-borne outbreaks of typhoid fever during the years 1910 to 1933, comprising 8,459 cases and 406 deaths. In Canada between the years 1912 to 1937 there were 47 milk-borne outbreaks of typhoid fever, affecting 6,701 persons and causing 692 deaths (Defries 1938); of these, the most serious was the Montreal outbreak of 1927, which caused, in the two waves that occurred between the middle of March and the beginning of July, no fewer than 4,849 cases and 489 deaths (Report 1927, Boucher 1927).

The organisms may gain access to the milk from the imperfectly cleansed fingers of attendants in the milking shed or dairy, or from contamination of milking utensils with infected water. Since both typhoid and paratyphoid bacilli can multiply in milk at ordinary atmospheric temperatures, even an initial contamination may prove dangerous. Though milk-borne outbreaks, like those due to water, are often characteristically explosive in their onset, scattered or "dropping" cases may be caused by milk, when the infection is confined to one or two churns or bottles or is intermittent.

Apart from liquid milk, *other dairy products* or substitutes such as cream, artificial cream, synthetic cream, custard and ice-cream, are frequent vehicles for the enteric group of organisms, particularly paratyphoid bacilli. Of the 40 paratyphoid outbreaks analysed by Savage (1942), 8 were due to liquid milk, 16 to cream and cream cakes, 2 to ice-cream, 1 to trifle, 1 to cream cheese, and 2 to other foods. Several outbreaks of typhoid fever in Canada have been ascribed to the consumption of unripened hard cheese made from raw milk handled by chronic carriers (Bowman 1942, Gauthier and Foley 1943, Menzies 1944). Most of these products are prepared in the home, a dairy, or a bakery, and become contaminated from human sources. One outbreak in Liverpool was traced to loaves of bread handled by a paratyphoid carrier (Frazer, Glover and Glass 1937). On the whole, the evidence suggests that ambulant cases or transitory carriers are most often responsible for contamination of food with paratyphoid bacilli, and chronic carriers for contamination with typhoid bacilli. Chronic carriers of

paratyphoid bacilli and ambulant cases of typhoid fever are said to be relatively uncommon (Scott 1941).

In outbreaks both of typhoid and of paratyphoid fever the typical symptoms of the disease may be preceded by acute gastro-enteritis coming on shortly after consumption of the infected water or food (see Savage and White 1925, Robertson 1936, Warren 1941). These early symptoms may pass imperceptibly during the following week or so into those characteristic of enteric fever, or there may be a remission before the onset of enteric symptoms, or there may be complete and lasting recovery.

Thus, in the Consett paratyphoid outbreak in 1940 which was due to home-made trifle infected from a profuse faecal and urinary excreter who was probably in the convalescent stage of an ambulant infection, of 56 patients admitted to hospital, 7 contracted enteric fever after an incubation period of six to twelve days; 17 suffered from gastro-enteritis coming on 12–72 hours after consumption of the trifle and gradually passed into the enteric state; 17 suffered from gastro-enteritis, recovered more or less completely, and then developed enteric fever after an interval of a few days; 9 suffered from gastro-enteritis and recovered completely; and 6 suffered from no symptoms at all but were proved bacteriologically to be infected.

Whether the initial gastro-enteritis represents the first reaction of the tissues to the specific infecting organisms, or whether it is due to other organisms capable of causing food poisoning, or to pre-formed toxins, is still in doubt.

Human hands are probably the principal agents in the conveyance of typhoid or paratyphoid bacilli from fæces to food; but there is another agent, the fly, which may be of considerable importance as a carrier when allowed access to infected excreta. Its activities in this direction are particularly dangerous in tropical countries, and under the imperfect sanitary conditions which often prevail among armies on active service. Reed, Vaughan and Shakespeare (1899) drew attention to the clear association between the prevalence of typhoid fever among the American troops in the Spanish-American War, and the exposure of excreta; and suggested that flies played an important part in the spread of the disease.

The mechanism involved in the carriage of *Salm. typhi* by flies has been studied experimentally by Firth and Horrocks (1902), Ficker (1903) and Graham-Smith (1910). The danger of contamination from the soiled feet, or proboscis, appears to be of relatively short duration; but the observations of Ficker and of Graham-Smith suggest that a far more important source of infection is provided by the fly which itself becomes infected, and carries the bacilli for some days in its intestinal canal. The observations of Faichnie (1909), who examined flies caught in infected areas, and isolated typhoid bacilli on several occasions from the crushed bodies of the insects after the exterior had been sterilized by flaming, point in the same direction (see also de la Paz 1939).

The Typhoid and Paratyphoid Carrier.—As has been indicated above, the ultimate source of enteric infection would appear, in all cases, to be the excreta of an infected human being, and this source is seldom remote. There is little evidence that typhoid or paratyphoid bacilli survive for any length of time outside the human body under natural conditions. The mode of survival of the bacilli throughout non-epidemic times, and the starting-point of outbreaks in localities which had long been free from the disease, remained in doubt until the early years of the present century, when the problem was solved during the intensive investigation undertaken in S.W. Germany under the auspices of Robert Koch. Horton-Smith

(1900) had previously recorded the case of a urinary carrier of *Salm. typhi*, but the full significance of the chronic carrier was not appreciated until the results of the German campaign were reported. (For an excellent description and discussion of these results see Ledingham and Arkwright 1912.) Koch's thesis, that the convalescent carrier would probably be found to be the main source of the persistence of infection within a community, was soon established on a firm basis by the findings of the Commission (Frosch 1903, von Drigalski 1904); and von Drigalski established the fact that the typhoid bacillus might lead a prolonged existence within the human body, and be excreted in the fæces.

Before quoting records of frequency, it is necessary to define our terms. In the older literature there is some confusion owing to the use of the same term in a different sense by different authors; but there is now fairly general agreement on the use of the word "temporary" or "transient" for carriers who excrete the bacillus for not more than a year, and the word "chronic" for carriers of over a year's standing. Temporary carriers are sometimes divided into "passive" carriers who excrete the organism without suffering from clinical symptoms, and "active" carriers who are suffering or convalescing from a clinically recognizable attack of the disease (see Scott 1941); but we can see little practical value in this distinction and we shall not employ these terms ourselves. There is some serological evidence to suggest that persons may harbour the infecting bacilli in the tissues for a long time without excreting them in the urine or fæces (see Pijper and Crocker 1943). Though the term "carrier" is strictly applicable to such persons, it would in practice be misleading to use it in this sense without some qualification, such as "closed." Excretion, even though only intermittent, is always regarded as part and parcel of the carrier state. It would, of course, be difficult to prove that excretion never occurred; and it is wiser to regard carriers of this type as potential excreters.

In considering the frequency of carriers we must realize that our technique of demonstrating typhoid and paratyphoid bacilli, especially in the fæces, is far from perfect. With the great technical improvements that have resulted in recent years from the introduction of more selective media, the idea has been growing that intermittency of excretion is less frequent than used to be thought, particularly in paratyphoid carriers (see Holt and Wright 1942). Though the methods now in use permit the detection of small numbers of organisms in the fæces more readily than before, it may be doubted whether their application will lead to any substantial modification of our estimate of the proportion of permanent carriers of typhoid bacilli. Many of these excrete the organisms in large numbers; and of the remainder many can be detected by the older media provided repeated examinations are made. Our knowledge, however, is still very deficient, and all our conclusions must be expressed with caution. We may deal first with the *typhoid carrier*.

Lentz (1905) found that 4·5 per cent. of 400 typhoid convalescents excreted *Salm. typhi* for more than 10 weeks, and 3 per cent. for longer than 13 months. Brückner (1910) found 12 carriers among 316 persons who had suffered from typhoid fever in previous years. Kayser (1907) carried out a re-examination of specimens of urine and fæces from 101 persons who had passed through an attack of typhoid fever at least one year earlier, and had been discharged as free from bacilli; 3 of these were found to be again excreting the infecting organism. Gill (1927) refers to the finding in Alabama of 9·5 per cent. of chronic typhoid carriers among a group of 348 persons who had suffered from typhoid

fever or from continued fever of several weeks' duration more than a year previously. Gray (1938) in Mississippi found that of 244 proved cases of typhoid fever, 8 continued to excrete the bacilli for over a year; it is to be noted that several patients excreted the bacilli for 3 to 9 months after recovery, but ceased to do so after 12 months. Ames and Robins (1943) in New York State refer to 90 chronic carriers resulting from 3,130 typhoid patients notified during the years 1930 to 1939.

From these figures it is fairly clear that about 3 per cent. of recognized clinical cases of typhoid fever become permanent carriers, though the proportion may in some places be higher.

Klinger (1909), in summarizing the results obtained to that date, gives records of 431 carriers; 211 of these did not excrete the bacilli for more than three months; 220 excreted them for a longer time. The distribution of these carriers, according to sex, and according to the presence or absence of a history of typhoid fever, was as follows:

	Males.	Females.
Carriers of less than 3 months' duration		
(*a*) History of attack	31	61
(*b*) No history of attack	58	61
Carriers of more than 3 months' duration		
(*a*) History of attack	33	143
(*b*) No history of attack	5	39

Two points of interest emerge from this distribution: (*a*) the high proportion of carriers in the first group in which there was no history of a previous attack, and (*b*) the striking preponderance of females among the second group of carriers. The latter point is of particular importance; and it may be noted that the difference between the sexes in this respect is of the same order as the difference in the occurrence of gall-stones. Klinger's data also show that transitory carriers occur mainly in children and young adults, chronic carriers among those in middle or later life.

Our information on the frequency of typhoid carriers among atypical cases, contacts, non-contacts in epidemic or endemic areas, and the population at large, is somewhat scanty, but it is sufficient to indicate that the distribution is of the general type discussed in Chapter 56.

Billet and others (1910) record the isolation of *Salm. typhi* from a high proportion of clinically atypical cases, during an outbreak of typhoid in an infantry regiment. The bacillus was isolated from the blood in 7 of 39 suspects, and from the fæces in 13 of 64 (20·3 per cent.) Semple and Greig (1908) isolated *Salm. typhi* from the fæces of two nursing orderlies, in typhoid wards, who had never shown any clinical evidence of the disease.

Klinger (1906) examined the excreta of 1,700 persons, living in an area in which typhoid fever was endemic, and isolated *Salm. typhi* in 15 cases. Eleven of these presented no clinical symptoms, either before or after the isolation of the bacilli. In 9 cases the bacilli were found once only. In 2 they were found 3 times; but in no case did they persist longer than 14 days. The other 4 carriers were of the chronic type. Two had passed through an attack of typhoid fever in previous years; from the remaining 2 no history could be obtained. Welch, Dehler and Havens (1925) report the discovery of 39 carriers of *Salm. typhi* during the examination of 1,076 persons engaged in the milk trade, in an area in which enteric fever had been prevalent for years. This carrier rate (3·6 per cent.) is exceptionally high, even for an endemic centre.

Among the population at large the carrier rate is probably very low. Minelli (1906) discovered one carrier among 250 inmates of the town prison of Strassburg—0·4 per cent. Prigge (1909) records 0·29 per cent. of carriers among a sample of 10,841 persons in Saarbrücken. Rosenau, Lumsden and Kastle (1909) found 3 carriers among 993 persons in

Washington. These figures are curiously similar, but the actual variation in the frequency of carriers among the general population is probably wide, and all we can safely conclude is that the average frequency is well under 1 per cent. In many localities it is probably considerably less. In New York State, exclusive of New York City, Ames and Robins (1943) calculated that in 1940 there were about 42 typhoid carriers per 100,000 population.

On the main point at issue the evidence leaves no doubt. Within any community in which enteric fever is endemic, there will be found transient or chronic carriers, who are acting as foci of infection; the isolation of every overt case of illness would not suffice to stamp out the disease.

With regard to contact cases Klinger (1909) records some interesting observations on the period of the disease at which infection is transmitted to the contact. In an investigation of 812 such cases he reached the conclusion that the distribution, in time, of the contact infections was as shown in Table 135.

TABLE 135

Period of Disease.	No. of Contact Cases.	Period of Disease.	No. of Contact Cases.
Incubation period:			
1st week	33	4th week	59
2nd ,,	150	5th ,,	34
Illness:		6th ,,	22
1st week	187	7th ,,	14
2nd ,,	158	8th ,,	16
3rd ,,	116	9th ,,	15
		10th ,,	8

It is obvious that the evidence on which such figures are based must be largely circumstantial. If they are correct it would appear that 183 of 812 contact cases, or more than 20 per cent., were infected during the incubation period of the primary case—at a time when the disease could not have been diagnosed, and when opportunities for its spread would be increased by the fact that the infected person would not be confined to bed. To such primary carriers (*i.e.*, those in the incubation stage of the disease) must be added the relatively numerous ambulatory cases of mild and atypical infection which occur during any extensive epidemic.

Turning now to the *paratyphoid carrier*, we find our evidence less well documented.

Leishman (see Savage 1942) analysed the results obtained at the central enteric depôt at Addington Park during the war of 1914–18. Of 1,425 cases of paratyphoid B fever, 43 (3 per cent.) were found to be still excreting the organisms after six months. At the German military convalescent depôt at Spa, Bumke (1926), who studied 338 fæcal carriers of paratyphoid B bacilli, found that 60–70 per cent. of them ceased to excrete the organism within three months, and 10–20 per cent. within three to six months; 20–30 per cent. were still excreting the bacillus after six months. In an outbreak at Liverpool, Glass and Wright (1937) found that the rate of clearance of paratyphoid bacilli from the fæces was most rapid during the second month; about 4 per cent. of convalescents were still excreting the organisms after 15 weeks. In a later outbreak at Liverpool, described by Holt, Vaughan and Wright (1942), the proportion of patients who continued to excrete paratyphoid bacilli after 16 weeks was 5 per cent. The rate of clearance, however, may be much more rapid. In the Bristol outbreak of 1940, for example, described by Davies, Cooper, Wiseman and Davies (1940) the proportion of carriers had fallen to 6·9 per cent.

after six weeks, as opposed to figures of 67 and 44 per cent. respectively for the two Liverpool outbreaks just quoted. In the Kettering outbreak described by Gell and Knox (1942) 3·6 per cent. of the patients were still excreting paratyphoid B bacilli after seven months.

The proportion of chronic carriers of paratyphoid B bacilli is still a matter of conjecture. Gill (1927) mentions that among 348 persons who gave a history of typhoid fever or of continued fever a year or more previously, 12 carriers of paratyphoid A or B bacilli were found. There is reason to believe that most of these were paratyphoid A carriers, but the exact figures are not given. All we can say at present is that chronic carriers of paratyphoid B bacilli do occur, but that their frequency is unknown.

There is little exact information on the duration of excretion of paratyphoid A bacilli, but the observations of Bumke (1926) suggest that these organisms disappear from the fæces at a considerably greater rate than typhoid bacilli.

In regard to the danger of the chronic carrier, it is only necessary to say that the literature contains numerous and well-authenticated records of their activities. For accounts of such classical instances as the case of the Strassburg Master-Baker's Wife, the case of the Folkestone Milker, or the case of " Typhoid Mary," the student is referred to the excellent monograph of Ledingham and Arkwright (1912), and to a paper by Soper (1939). It need only be noted that in these, as in almost all subsequent cases, the carrier who has achieved publicity has been in some way concerned with the handling of food, and that a large proportion of milk-borne epidemics, or small outbreaks due to the consumption of such food-materials as ice-cream, have been traced to a carrier who has been concerned in their handling or transport.

It may be added that, in searching for a typhoid carrier among a given sample of the population, much help will be obtained by testing the serum of all suspects for agglutinins before proceeding to the cultural examination of fæces and urine. A carrier often shows the presence of H or O agglutinins, even though only in low titre; but these will afford little or no useful information if the person has been inoculated with T.A.B. The observations of Felix (1938*a*) have shown that much greater value attaches to the demonstration of Vi agglutinins. In chronic typhoid carriers the frequency of a positive Vi reaction in the serum appears to be very high. Felix's observations have been confirmed by Eliot (1940), Eliot and Cameron (1941), Klein (1943) and several other workers (see Pijper and Crocker 1943). It is clear, however, that though probably over 90 per cent. of chronic carriers contain Vi agglutinins in their serum, the presence of Vi agglutinins is in no sense diagnostic of the carrier state.

Horgan and Drysdale (1940), for example, in the Sudan found that 46·5 per cent. of sera taken for the Kahn test contained Vi agglutinins in a titre of 1 : 5 or higher. Davis (1940) in Southern Rhodesia obtained a figure of 7·5 per cent. for sera taken from 656 natives at random, but in only one of the 26 positive subjects examined was he able to demonstrate the presence of typhoid bacilli by culture. Eliot and Cameron (1941), searching for carriers in Maryland, found 8 persons among 100 studied with a Vi serum of 1 : 20 or over; from only 4 of these were typhoid bacilli isolated from the fæces. Pijper and Crocker (1943) in South Africa examined the serum of personnel employed, or applying for employment, in dairies, waterworks, or the General Hospital, Pretoria. Of 588 white persons examined, 4·1 per cent., and of 1,938 natives examined, 5·7 per cent. had Vi serum agglutinins in a titre of 1 : 10 or higher. Three stool and urine cultures were made on all the white reactors without any success. A varying number of examinations were

made on forty of the native reactors, but typhoid bacilli were isolated from the urine of only two of them. Of 149 contacts of typhoid fever cases, 26 per cent. gave a positive Vi reaction, but in only 3 of them were typhoid bacilli demonstrated by culture—again in the urine.

On the whole, experience in Great Britain and the United States suggests that in the search for chronic carriers the Vi serum test is a most valuable preliminary measure. Very occasional carriers, infected perhaps with a strain of bacillus devoid of Vi antigen (see Rauss 1939), may have no Vi agglutinins; and some persons with a positive Vi serum test may prove persistently negative on culture. In such instances it is wise to examine the duodenal juice, since there is reason to believe that biliary carriers may excrete typhoid bacilli in the fæces intermittently, or in too small numbers to be detected by any of our present methods. Occasional Vi-positive carriers may be suffering from a bone lesion, and cannot be expected to show the presence of typhoid bacilli in the fæces or urine, though, of course, they may do so. Disappearance of Vi agglutinins from the blood of a carrier is suggestive of cure.

The technical demonstration of Vi agglutinins is most conveniently carried out by making use of a strain of typhoid bacillus that will respond only to Vi agglutinin in the serum (see Felix 1938*b*). Final serum dilutions should be put up at 1 : 5 onwards, the tubes should be incubated at 37° C., not at 50° C., for 2 hours, and the readings should be taken after a further 22 hours at room temperature. Living bacilli may be used, but the Oxford Standard suspension, made from killed organisms, is safer and more convenient; it does not usually prove satisfactory, however, for more than two months after its preparation.

In tracking down carriers of typhoid and of paratyphoid fever, whether transitory or permanent, and in establishing the relation of different cases to each other, the *bacteriophage method of typing* the bacilli is of very great service. As this subject has already been discussed in Chapter 30, we need do no more here than remind the reader that the susceptibility of a given strain to lysis by the bacteriophage is intimately associated with the Vi antigen, and that the different bacteriophage types are remarkably specific. For a description of the types of typhoid and paratyphoid bacilli prevalent in Great Britain and the United States, and of the value of the method in epidemiological investigations, the reader is referred to papers by Lazarus (1940), Felix (1943), Felix and Callow (1943), and Bradley (1943), and for a review of the carrier problem in general to the monograph by Browning and his colleagues (1933).

The Effect of General Sanitation on the Prevalence of Typhoid Fever.

Having discussed the part played by the chronic carrier of enteric infection it will be convenient to consider briefly the changes in the incidence of typhoid fever which have occurred during the last 50 years, and their relation to the improvements which have taken place, during the same period, in the sanitary organization of civilized communities.

One of the most striking phenomena in the public health annals of this period has been the steady decline of enteric fever as an important item in the mortality statistics. In 1870 there were 388 deaths from enteric fever per million living in England and Wales, and 233 deaths registered as "ill-defined." In 1880 the enteric deaths had fallen to 261 per million, and the "ill-defined" deaths to 58, the latter probably as the result of better diagnosis. In 1890 the enteric deaths had fallen to 179 per million, and the "ill-defined" to 13. In Table 136, for

which we are indebted to Miss Woods, are set out the death rates at ages from enteric fever in England and Wales, during the first 27 years of the present century. It will be noted that, for the first decade (1901–10), the death rate for males at the most susceptible age period (20–25) is no higher than for the population as a whole in 1890. Since 1910 the mortality from enteric fever has fallen rapidly; and in 1927 it had reached almost negligible proportions—less than 10 per million living.

TABLE 136

ENTERIC FEVER: ENGLAND AND WALES. DEATH RATES PER MILLION

	0–	5–	10–	15–	20–	25–	35–	45–	55–	65–	75 and up
Males:											
1901–10 .	32	52	71	137	179	178	142	104	80	40	17
1921–24 .	3	6	10	20	19	20	17	16	16	13	3
1925 .	6	5		16		14	10	9	11	9	4
1926 .	2	5		11		16	14	15	10	11	7
1927 .	2	8		12		11	12	14	12	5	—
Females:											
1901–10	30	59	81	100	99	97	86	67	50	29	10
1921–24	3	9	11	19	18	16	15	13	7	9	3
1925 .	1	8		12		12	13	11	12	7	7
1926 .	2	5		12		7	12	11	11	4	7
1927 .	4	3		11		9	10	14	12	6	4

This fall has not, however, been equally rapid in all Western countries. Gay (1918) points out that the mortalities in European cities during the decade 1901–10 varied from 17 per million in Stockholm to 337 per million in St. Petersburg. The average figure for the 33 largest European cities during this period was 65 per million, while the average figure for the 57 largest American cities during the last year of the decade was 195·9 per million.

These variations in place and in time are associated with characteristic differences in sanitary organization. As Gay points out, prior to 1880 or thereabouts, typhoid fever was a disease of cities, the incidence varying directly as the density of population, as exemplified by the figures for Munich and the surrounding district; these show the highest incidence in the city garrison, a somewhat lower incidence in the city as a whole, and a still lower incidence in the surrounding rural area. After this time, however, the sanitation of large cities rapidly and steadily improved, especially with regard to the provision of a pure water supply, and the efficient disposal of excreta and sewage. This improvement in sanitation has more than compensated for the density of population, and the result has been a shift in the incidence of enteric fever from the populations of large towns to rural communities, living under more primitive sanitary conditions.

Godfrey (1928) records some interesting figures with regard to the present incidence of enteric fever in New York City and State. In New York City itself the cases—not deaths—number about 23 per 100,000 living. In towns with populations of 10,000-20,000 the incidence is about 70 per 100,000, in towns with populations of 5,000-10,000 it is about 63, in towns under 2,000 about 48, and in very small towns and villages about 42. Thus, while enteric fever is less frequent in New York City than elsewhere in the State, it is at

the present time a disease of the small town, rather than a rural disease in the strict sense of that term. This is probably due to the fact that the small town has failed to keep its sanitary organization abreast of its growth; so that the water supply, sewage disposal, and milk control are inadequate to protect a community rapidly increasing in density of population.

Godfrey includes a valuable table showing the incidence of enteric fever at ages, and the percentage fatality in each age group. Information of this kind is not available for many communities, and we reproduce his figures in Table 137.

TABLE 137

INCIDENCE AND FATALITY OF ENTERIC FEVER IN DIFFERENT AGE GROUPS (after Godfrey).

Age Group.	Incidence (percentage of cases at all ages).	Case Fatality Percentage.
Under 5	4·5	8·4
5–9	13·8	4·4
10–14	14·3	6·4
15–19	14·2	10·2
20–24	12·0	12·5
25–29	9·7	13·5
30–34	7·7	16·4
35–39	6·3	15·2
40–44	5·4	15·2
45–49	3·9	19·9
50–54	3·3	22·9
55–59	2·0	22·8
60 and over	2·9	36·5

Enteric fever, at the present time, is thus a disease with its maximum incidence in adolescence; but the case fatality increases throughout life, save that children under 5 show a higher case mortality than children between 5 and 15.

In addition to the striking fall in the incidence of enteric fever as a whole, there was during the post-war years a change in the sex incidence, and in the prevalent bacteriological type of infection. Thus it was noted by Chauffard and his colleagues (1921), Weigmann (1926) and Knorr (1927) that after the middle period of the war the incidence of enteric fever was higher among women than among men, thus reversing the normal sex incidence, as universally experienced before the war. There can be little doubt that this shift was the result of the experience undergone by the male sex between 1914 and 1918. Thus, in an epidemic at Pforzheim in 1919 (Knorr 1927), the lower incidence among males than among females commenced at age 19 and ended at age 50, indicating very clearly the effect of military service. It seems probable that some part, at least, of the present advantage of the male sex was referable to the antityphoid vaccination of the troops during the war period; but there are facts which suggest that this is not the whole story. In Schleswig-Holstein, for instance, during the period 1914–24, the advantage of the males extended to enteric fever caused by *Salm. paratyphi B*, while the German troops, unlike the French and English, were immunized only against *Salm. typhi*. It is possible that this heightened average resistance of the male may have been due to mild or atypical infection while on war service, but the question must for the moment remain an open one.

Prophylactic Immunization against Enteric Fever.

Antityphoid vaccination in man was initiated by Wright in 1897 (see Wright and Semple 1897, Wright 1902, 1908)—though the observations of Pfeiffer and Kolle (1896) have been held by some to establish a claim to priority—and has since been tried under field conditions on the largest scale. The recorded results strongly

support the view that it significantly reduces the incidence of enteric infection in environments in which such infection is particularly likely to occur.

The most impressive figures are those collected by the Antityphoid Committee (Report 1913), referring to the incidence of typhoid fever among inoculated and uninoculated troops stationed abroad. These figures have been analysed in a valuable paper by Greenwood and Yule (1915), to which reference should be made by all those who are interested in the general question of the interpretation of data of this kind. Employing the method of the fourfold table, and including as inoculated all those who had received typhoid vaccine at the time of the last available return, the data are set out in Table 138.

TABLE 138

	Not Attacked.	Attacked.	Total.
Inoculated. . .	10,322	56	10,378
Not inoculated .	8,664	272	8,936
Total	18,986	328	19,314

$\chi^2 = 180{\cdot}38.$
P= less than 0·0001.

The value χ^2 is a measure, devised by Pearson, of the probability that the distribution actually observed might have arisen as the result of chance; as χ^2 increases, this probability decreases. The value P gives this probability in the usual numerical form (*i.e.*, in this particular case the odds are greater than 9,999 to 1—actually they are much greater —against the observed distribution having arisen as the result of chance).

War conditions provide an admirable breeding ground for typhoid and paratyphoid infections; and it might have been expected that 1914–18 would have yielded a final proof of the efficacy of antityphoid inoculation, and a close measure of its exact protective value. They did, in truth, greatly strengthen the presumptive evidence in its favour —we cannot reasonably suppose that the whole of the vast difference between the deadly rôle of typhoid in the Boer War (105 cases per year per 1,000 of strength) and its relative insignificance among the huge armies on the Western Front 15 years later (2·35 cases per year per 1,000 of strength—see Harvey 1929) was wholly due to better sanitary conditions. But the exigencies of war, the impossibility of getting complete figures for the inoculated and the uninoculated exposed to risk, and the fact that the proportion of inoculated men rose, in the British Army, to well over 90 per cent. by the end of 1915, rendered impossible the collection of mass figures of a kind suitable for detailed statistical analysis. The general trend of the evidence is not, however, in doubt. Thus (see Harvey 1929) the year 1915 provides figures for the percentage of inoculated men in the Army in France and the cases of typhoid in the inoculated and the uninoculated, from which the incidence in each group can be calculated. The incidence among the inoculated was 9·5 per 10,000, among the uninoculated 103·52 per 10,000. During this period the men were inoculated against typhoid only. The incidence rates for paratyphoid fever were, among the inoculated 21·53 per 10,000, among the uninoculated 39·84 per 10,000. This suggests some degree of group protection against paratyphoid infection—a result that would hardly have been expected on immunological grounds—but the wide difference in the incidence ratios (10·90 : 1 in favour of the inoculated in the case of typhoid and 1·85 : 1 in the case of paratyphoid) provides additional support for the view that the recorded figures do in fact represent a saving in morbidity due to the typhoid vaccine.

There is evidence, as might reasonably be expected, that the decrease in morbidity was associated with a decrease in case fatality, at least so far as typhoid fever was concerned. The case-fatality rate among 1,728 inoculated and infected men in the British armies in France was 4·57 per cent.; among 703 uninoculated men it was 18·35 per cent.

Curiously enough this finding was not paralleled in paratyphoid infection: among 1,357 infected men who had been inoculated with T.A.B. vaccine the case-fatality rate was 1·25 per cent.; among 2,694 men who had not been inoculated with T.A.B. vaccine it was 1·34 per cent. The difference in the case fatality of typhoid in inoculated and uninoculated men is borne out by the figures recorded by Pfeiffer (1922) for the German Army; 12–20 per cent. among the uninoculated, 2–3 per cent. among the inoculated.

Ancillary evidence, which may perhaps be adduced in support of the efficacy of anti-typhoid vaccination, is provided by the curious change in the sex incidence of enteric infection in the years following the war that has been referred to on p. 1550.

The results so far recorded were obtained with vaccines prepared from ordinary strains of typhoid and paratyphoid bacilli. The observations, however, of Felix and his colleagues on the Vi antigen of the typhoid bacillus (see p. 1525) pointed to the importance of selecting for vaccine preparation strains that were rich in this particular antigen, if the maximum protective effect was to be obtained. Perry, Findlay, and Bensted (1933, 1934*b*), who carried out experiments on mice, likewise reached the conclusion that only fully virulent smooth strains could be relied upon to induce a satisfactory degree of immunity. Immunization with an avirulent smooth strain was almost as ineffective as that with a frankly rough variant. They differed, however, in failing to observe the extreme degree of lability of the Vi antigen that had been described by Felix and Pitt (1934*a*). In fact, they found that, so long as the strain employed was of the fully virulent smooth type, an ordinary heat-killed vaccine preserved with 0·5 per cent. phenol proved fully effective. As a result of their work, the British Army vaccine has since been prepared from freshly selected smooth fully virulent strains of typhoid and paratyphoid bacilli, grown on agar for 48 hours at 37° C., washed off with saline, killed by heating for 1 hour at 53° C., and preserved with 0·5 per cent. phenol. It is standardized to contain 1,000 million *Salm. typhi*, and 750 million each of *Salm. paratyphi A* and *B* per ml. The usual dosage for an adult male consists of two inoculations subcutaneously of 0·5 and 1·0 ml. respectively at about 10 days' interval.

The value of T.A.B. vaccine prepared in this way received further confirmation during the second world war (Boyd 1943*a*).

Briefly, it was found that Italian prisoners of war taken in the first Libyan campaign, most of whom had been inoculated previously with an Italian T.A.B. vaccine, suffered from typhoid fever during the winter of 1940–41. All prisoners were therefore inoculated or re-inoculated with Italian T.A.B. vaccine. In spite of this, another wave of typhoid fever occurred in May to September, 1941, along with an outbreak of paratyphoid A fever during June to October. The British Army T.A.B. vaccine was therefore given in the usual two doses. The outbreak rapidly waned, and infection remained low all through the summer of 1942. With the influx in November and December, 1942, of fresh prisoners from the El Alamein battle, a fresh wave occurred. On the other hand, among the British prisoners of war in the Benghazi camp, though there were about 11,000–12,000 cases of dysentery in a total strength of 16,000–24,000, no cases of enteric fever were notified during the four months June to October, 1942. These two pieces of evidence: (1) the occurrence of endemic and epidemic enteric fever among the Axis forces, not controlled by the Italian T.A.B. vaccine, but apparently controlled and prevented by the British Army T.A.B. vaccine; and (2) the absence of enteric fever among British prisoners of war in spite of most unsanitary conditions and the presence of enteric fever in their captors—are difficult to explain except on the assumption that the British Army T.A.B. vaccine affords a high degree of protection against enteric fever.

This vaccine appears to be very effective in practice, but it does not as a rule provoke the appearance of circulating Vi antibody when given subcutaneously, though it is said to do so on intravenous inoculation (Climie 1942). Felix (1941), therefore, endeavoured to improve on it by preparing a vaccine in which the Vi antigen was subjected to less rigorous treatment than that which it receives in the heat-killed phenolized vaccine. This he succeeded in doing by killing the organisms with 75 per cent. alcohol and preserving them in 25 per cent. alcohol. Comparative trials of the two vaccines on human beings showed that, after administration of the alcoholized vaccine, Vi antibodies were demonstrable in a relatively high proportion of subjects, whereas after the ordinary vaccine they could seldom be found (Felix, Rainsford and Stokes 1941). The dosage recommended for the alcoholized vaccine is half that of the heat-killed vaccine, namely 0·25 and 0·5 ml. for an adult male, the interval between the two injections being preferably three weeks. The value of this vaccine has not yet been established in the field, but there is no reason to suspect that it will be less, and some reason to expect that it may be greater, than that of the heat-killed product. It has the advantage over this product of giving rise to rather less local, and considerably less constitutional reaction (Climie 1942, Report 1942*b*).

In South Africa an endotoxoid T.A.B. vaccine has been extensively used, prepared according to the method described by Grasset and Gory (1927*a*, *b*) and Grasset (1931, 1935). This consists essentially in washing off a 48-hour agar growth with distilled water, killing the organisms by heat at 58° C. for 30 minutes, breaking them up by four successive heatings and freezings, and finally rendering the endotoxin so obtained non-toxic by incubation for a month in the presence of 0·7 per cent. formalin. The endotoxoid can be given in larger doses than vaccines of whole bacilli. According to Grasset (1938*b*) the vaccine has been used for the inoculation of about 400,000 persons with more satisfactory results, judged by the diminution in the case incidence and case mortality rates, than those previously obtained from ordinary T.A.B. vaccine. Grasset's claims seem to be borne out by the experience of the South African troops in the North African campaign, which fared as well as those inoculated with the British Army vaccine (Boyd 1943*b*).

Kourilsky, Kourilsky and Boivin (1939) tried to make a vaccine from the pure glycolipoid somatic antigens of the typhoid bacillus, but were unable to reduce the toxicity of the preparation sufficiently. More recently, however, Morgan, Favorite, and Horneff (1943) report success in the preparation of a suitable purified antigen.

There is little exact knowledge on the *keeping quality* of ordinary heat-killed vaccine preserved with 0·5 per cent. phenol or tricresol, but so far as can be judged from their ability to stimulate the production of agglutinins in rabbits or to protect mice against infection with living organisms, vaccines stored at a temperature of under 10° C. seem to undergo little deterioration in potency over a period of three years (McCoy and Bengtson 1920, Perry, Findlay and Bensted 1934*a*, Mishulow, Mowry and Stocker 1937, Babudieri 1939).

Whatever vaccine is used it is desirable, if immunity is to be maintained at a high level, to re-inoculate subjects every 2 to 4 years. For this purpose one dose is sufficient. Siler and Dunham (1939) of the American Army recommend a single dose of 0·1 ml. (100 million organisms) of the phenolized vaccine injected intradermally; according to their findings, this provides an adequate stimulus, and gives rise to less local and constitutional reaction than the larger dose which is usually given subcutaneously. The alcoholized vaccine is not suitable for intradermal injection.

The *oral administration* of typhoid vaccine, which was suggested by the observations of Besredka (see Chapter 53), has been tried fairly extensively, but the results so far obtained have not been sufficiently encouraging to justify its substitution for the subcutaneous method (see de Mello *et al.* 1931, Grasset 1938*b*).

In the chapter on herd immunity we described experiments on mice; and arguing, with the necessary caveat, from mice to men, we drew the tentative conclusion that antityphoid inoculation, carried out by the best technique at present available, would form a poor substitute for the ordinary methods of sanitary control as applied to a population exposed to a severe and continuous risk of infection. There seems no reason to modify this view in the light of the recorded results on man. Inoculated men appear to do much better than inoculated mice, but they are never exposed to such severe and continuous risk. Even with their advantages in this respect there is no evidence that the inoculation of all those at risk will stamp out the disease, though it will greatly reduce both its incidence and its fatality. As a method of decreasing the chances of infection or death run by persons who are exposed to a serious but not overwhelming risk for a limited period of time, antityphoid inoculation must be regarded as a very valuable prophylactic measure. (For a review of immunization against typhoid fever, see Siler *et al.* 1941).

Prophylactic Vaccination during an Epidemic.

The beneficial effect on the morbidity rate of vaccinating contacts during the course of sporadic outbreaks of typhoid fever has been reported by Ramsey (1935). His observations have been quoted as a precedent for similar treatment of persons exposed to infection in water or milk-borne outbreaks of the disease. The two cases are not strictly parallel. There is reason to believe that vaccination during the incubation period of the disease may, instead of protecting, induce the opposite result, namely the so-called "provocation" typhoid. For this reason Topley (1938) has suggested that the use of passive immunization with antityphoid serum would be more appropriate for such persons. Possibly, combined active and passive immunization, such as has proved successful in the treatment of diphtheria epidemics (see p. 1401), might be even more satisfactory, but we must await the trial of this method before recommending it for general use.

The Treatment of Typhoid Fever with Antityphoid Sera.

There are various references in the literature to the treatment of typhoid fever by the injection of antisera prepared by immunizing horses with cultures or extracts of typhoid bacilli, but until recent years little success appears to have been achieved by this method. With the increase in knowledge, however, of the antigenic structure of the typhoid bacillus that resulted from the demonstration of the H, O and Vi antigens, and from the extraction of the O and Vi antigens in relatively pure form by chemical means, a way was opened up for the preparation of sera containing the desired antibodies and for checking the amount of individual antibodies in sera by suitable animal tests. Grasset (1930, 1931, 1938*a*), in South Africa, reported favourable results from the use of an antiserum prepared against the somatic antigen. In 1938 he stated that the serum had been tried on about 3,500 cases of typhoid fever, and had reduced the case mortality from 20 to 10 per cent. In cases in which it was administered during the first three days of the disease, the serum reduced the case mortality to 3 per cent. Felix (1935)

suggested the use of a serum containing Vi antibody in addition to the O antibody. Preliminary trials carried out in Palestine, in which a few control cases were treated with normal horse serum, yielded promising results. Favourable reports on the value of such a serum have since been published by Robertson and Yu (1936) at Shanghai, McSweeney (1937) at Dublin, Cookson and Facey (1937) and Hodgson (1944) in this country, Pijper and Crocker (1939) at Johannesburg, and Landor (1941) at Singapore. The serum should be given to adults in a dose of 33 ml. on two or three successive days. Intramuscular injection is the rule, but the intravenous route may be preferable for the first dose in severe cases. According to Felix (1935) the Vi antibody has an anti-infective action, suppressing multiplication of the typhoid bacilli; the O antibody, on the other hand, is chiefly responsible for neutralizing the endotoxin. This interpretation is not entirely borne out by the observations on mice of Grasset and Lewin (1937), Boivin and Mesrobeanu (1938*c*), and Longfellow and Luippold (1943), all of which suggest that the O antibody has some anti-infective power; but there is general agreement on the protective value of both antibodies. The mode of preparation of the serum has been described by Felix and Petrie (1938); and the method of titration and of assessment in terms of provisional units of Vi and O antibody has been laid down by Felix (1938*b*). The real therapeutic value of the serum will never be established until an adequate series of treated and control cases are observed together. Whether, in view of the favourable reports on the serum, it is too late to make such a trial, must remain open to question.

Chemotherapy in Enteric Fever.

Though Buttle and his colleagues (1937) found that the administration of sulphanilamide protected mice against multiple lethal doses of typhoid and paratyphoid bacilli, none of the sulphonamides has yet been shown in practice to have any beneficial action on patients suffering from enteric fever (Report 1943*b*). Numerous drugs have been tried for the treatment of chronic typhoid and paratyphoid carriers, but in spite of occasional favourable reports on the use of iodophthalein (Saphir, Baer and Plotke 1942) or of sulphaguanidine (Loewenthal and Corfield 1943), the medical treatment of these carriers has so far met with little success.

Enteric Infection in Animals.

It is impossible to consider in any detail the numerous varieties of enteric infection which are known to occur among the lower animals under natural conditions. References to the relation of the different species or types, within the typhoid-paratyphoid group, to various forms of animal infection will be found in Chapter 30. It may be noted that the bacterial species with which we have so far been concerned in this chapter are not natural pathogens of animals; while the species and types which produce enteric infection in swine, rats, mice, etc., usually give rise to acute gastro-enteritis when ingested by man (see Chapter 72).

The rôle played by *Salm. choleræ-suis* in hog cholera is discussed in Chapter 88.

Bacillary White Diarrhœa of Chicks.—References to several papers dealing with *Salm. pullorum*, the causative organism of this disease, and with the lesions which it produces in chicks and adult fowls, will be found in Chapter 30. A useful review of the literature is included in a paper by Rice (1926); and an account of the epidemiology of the disease, and of its control in flocks, is given by Dalling,

Mason and Gordon (1928). Apart from its great economic importance, the disease is of interest in that it affords an example of congenital infection *via* the egg, and an illustration of the application of bacteriological principles in the control of infective disease among live-stock.

The first cases of disease among an infected brood usually occur soon after hatching, and the outbreak often assumes epidemic proportions within a few days or weeks. Susceptibility to the natural spread of infection, in its severe form, would seem to be confined to the first few days after hatching. The incubation period is stated to vary from 4 to 10 days, though Rice records experiments in which it was as long as 28 days. Birds which survive the first few weeks seldom contract the disease in its acutely fatal form. Apart from the whitish diarrhœa, from which the disease derives its name, but which is by no means invariably present, the symptoms consist in drowsiness, thirst, and lack of appetite. The average duration of the disease is 2 or 3 days ; and the mortality is high—on the average about 70 per cent. At necropsy the lungs may be congested : the liver is enlarged, and may, according to some observers, show an unusual degree of mottling ; the intestine usually shows well-marked catarrhal enteritis.

Birds which survive the acute attack, and probably others which have never suffered from the typical disease, frequently develop a persistent ovarian infection ; and it is carrier birds of this type which perpetuate infection from one breeding season to another. A considerable proportion of the eggs laid by such birds are infected with *Salm. pullorum* ; Kaupp (quoted by Rice) records nearly 20 per cent. of infected yolks among 3,510 fresh eggs examined. Thus, in an infected flock, each year's hatchings produce a high proportion of infected chicks, and the cycle is repeated from year to year.

According to Severens, Roberts and Card (1944) genetic factors play an important part in determining susceptibility to the disease. During the first 5–10 days of life there is an increase in resistance to experimental infection, which is far greater in some chicks than in others. The increase is accompanied by a rise in the absolute and relative numbers of circulating lymphocytes. Evidence is brought to show that procedures such as splenectomy or irradiation with X-rays, which lower the lymphocyte count, lead also to a diminution in the resistance of the host.

The problem of control clearly resolves itself into the elimination of the carrier hens and this has been rendered possible by the application of the agglutination test. Blood is obtained from the wing vein, and the serum tested against suspensions of *Salm. pullorum.* This organism is non-flagellated, and contains only O antigens : the conditions must therefore be adjusted to reveal agglutination of this type. It is customary to use living suspensions, but it seems likely that alcoholized suspensions would prove as sensitive and could more readily be standardized. Incubation should be prolonged for 24 hours, though the results are usually readable after 4 hours at 50° C. The titre usually taken as diagnostic of infection is 1 : 40 to 1 : 50. Adopting this standard, it would appear that some 90 per cent. of carrier hens can be detected (Rice 1926). Such tests may be carried out at any time, and the detected carriers should be killed. The essential point, in preventing the perpetuation of infection from one season to another, is the elimination of all carriers among the birds preserved for breeding. The whole flock should be tested when the hatching season is over ; those which show agglutinins should be killed, and those which give negative reactions should be retested.

Only birds which have twice reacted negatively, and whose previous history gives no reason to suspect infection, should be retained for breeding in the following year.

CHAPTER 70

BACILLARY DYSENTERY

Introductory

Together with plague, cholera, and influenza, dysentery has been one of the great scourges of the world. Though rapidly growing less common, it was at one time a fatal epidemic disease, dogging the footsteps of armies in the field, present in camp, gaol, and hospital, and decimating the white races in the tropics. "Wherever the general hygienic conditions are bad, wherever the soil is much fouled by excreta . . . , wherever many people are crowded together in one building or camp, where the food is coarse, monotonous or unsound, there, especially in tropical and sub-tropical climates," dysentery is liable to break out (Manson 1914).

Before the last quarter of the nineteenth century dysentery was regarded as a single, well-defined disease. In 1875, however, Loesch demonstrated the presence of parasitic amœbæ in the stools of dysenteric patients, and in 1883 Robert Koch observed these amœbæ in the intestinal wall of patients dying of dysentery in Egypt. The subsequent demonstration of amœbæ in liver abscesses of patients who were then suffering, or who had at some previous time suffered, from dysentery left little doubt that at any rate one of the causal agents of this disease was the *Entamœba histolytica*. In 1898–1901 Shiga in Japan, Flexner in the Philippines, and Kruse in Germany brought evidence to show that another type of the disease was due to a bacillus which was closely allied to *Salm. typhi*. Dysentery may also at times be caused by protozoa other than *Entamœba histolytica*, such as *Balantidium coli* and *Bilharzia mansoni* (see Manson-Bahr 1942).

In this chapter we shall deal exclusively with bacillary dysentery, referring our readers to textbooks on tropical medicine and protozoology for descriptions of the amœbic and balantidial types.

Historical.—Dysentery affords an illuminating example of a case in which the agglutination reaction was successfully employed to discover the causative agent of a disease.

Studying the epidemic of dysentery in Japan in 1896, Shiga (1898) isolated from the fæces and intestinal wall of dysenteric patients a Gram-negative, non-gelatin-liquefying coliform bacillus. This organism, which was cultivated from 34 patients, differed from the common *Bact. coli* in its failure to coagulate milk, and in certain other cultural properties. At the same time nine other organisms were cultivated. To ascertain which of them, if any, was causally related to the disease, Shiga tested the action of the patient's serum on each one of them. Only one of the types was agglutinated. This type was, moreover, never found in the fæces of patients suffering from other intestinal diseases such as typhoid or simple diarrhœa, nor was it agglutinated by the serum of such patients, or by the serum

of healthy persons. In the acute stage of dysentery it was present in almost pure culture in the blood-and-mucus stools; but during convalescence its isolation was difficult or impossible. This bacillus he called *Bact. dysenteriæ*. Though fatal to laboratory animals injected parenterally, it did not reproduce the characteristic symptoms of dysentery when given by the mouth.

In 1900 Flexner (1900*a*, *b*), then a member of the Commission sent out by the Johns Hopkins University to study the diseases prevailing in the Philippine Islands, reported the discovery of a bacillus closely resembling Shiga's.

A similar organism was discovered, also in 1900, by Strong and Musgrave working at Manila. In the same year Kruse (1900) in Germany described a bacillus that he had isolated from the fæces of 23 out of 24 patients suffering from dysentery.

There was at first considerable confusion with regard to the relation of these various strains to one another. This was finally elucidated by the investigations of Martini and Lentz (1902), who found that a serum prepared by the injection of a goat with Shiga's strain agglutinated Shiga, Kruse, and one of Flexner's strains (New Haven), but failed to react with Flexner's other strains (1 and Manila) or with Strong's bacillus. On the other hand, a serum prepared against Flexner I agglutinated Flexner I and Flexner Manila, but not Strong, Flexner New Haven, Shiga or Kruse. They likewise found that all of these bacilli were non-motile and non-flagellated. On a serological basis, therefore, they concluded that Shiga, Kruse, and Flexner New Haven were identical, and differed from Flexner I, Flexner Manila, and Strong; these two Flexner strains likewise differed from Strong's bacillus. This conclusion received striking confirmation from the further work of Lentz (1902); testing the sugar reactions of the dysentery bacilli, he was struck by the observation that Flexner I, Flexner Manila, and Strong all produced acid in mannitol, whereas Shiga, Kruse, and Flexner New Haven did not.

Lentz's work served to divide the dysentery bacilli into (1) the non-mannitol-fermenters—Shiga and Kruse; and (2) the mannitol-fermenters—Flexner I and Manila, and Strong. The former group was called the Shiga or the Shiga-Kruse group, the latter the Flexner group. (It is clear that Flexner isolated both the Shiga and Flexner types in the Philippines; but the one that bears his name is exclusively the mannitol-fermenting type.)

It will be noted that without the agglutination reaction it would have been extremely difficult to prove the ætiological rôle of the dysentery bacillus. This organism, unlike *Salm. typhi*, does not invade the blood stream, and cannot therefore be cultured from the blood. It does not reproduce the disease on injection into animals; and by cultural properties alone it is not easily distinguishable from closely allied organisms. The agglutination reaction, in conjunction with the invariable presence of this bacillus in the acute stages of epidemic dysentery, sufficed to differentiate it from other organisms and to indicate its pathogenicity to man.

Besides the Shiga-Kruse and the Flexner group, numerous other organisms have been found capable of giving rise to dysentery, such as *Sh. sonnei*, *Sh. schmitzi*, *Sh. newcastle*, *Sh. boyd*, and according to some workers members of the para-Shiga group (see pp. 1567–1569 and Chapter 29).

Epidemiology.

Bacillary dysentery is primarily an epidemic disease; but like most epidemic diseases it often occurs endemically. At present it is commoner in tropical than

in temperate climates, but this is largely due to lack of adequate sanitation and personal hygiene. In former times, when sanitary measures were not so well enforced as they are now, dysentery was widespread all over Europe; and in our own times it needed only a war with its accompanying indifferent sanitation to allow it to become rampant again. Wherever large numbers of men are in close contact for any length of time under poor hygienic conditions, dysentery may be expected. Thus it has always been, and to a certain extent still is, a disease of armies, gaols, hospitals, and asylums. Amœbic dysentery, on the other hand, occurs sporadically, and is mainly confined to tropical countries.

Though in the past recognition has been accorded almost solely to dysentery in its epidemic form, increasing attention has been paid of late years to the endemic disease. The careful study carried out by Bojlén (1934) in Denmark has shown that in that country the disease is widespread and of frequent occurrence. Similar conclusions have been reached in the United States as the result of surveys by McGinnes and his colleagues (1936) in Virginia, and Watt, Hardy and DeCapito (1942) in New Mexico, Georgia, and Puerto Rico. The real incidence of the disease is difficult to assess, since in most countries only the severe cases are notified. In Great Britain the reported cases rose from 683 with 155 deaths in 1928 to 4,167 with 139 deaths in 1937; but there is strong reason to believe that the actual number of cases was considerably in excess of these figures. As Bojlén (1934) in Denmark and Charles and Warren (1929) in this country have shown, the majority of the recognized cases occur in children. The sexes are attacked equally. The case mortality varies widely according to circumstances and particularly to age. It is especially high in mental hospitals, in times of famine, and in infections due to the Shiga bacillus. In the first three months of life it tends to be high, but it decreases gradually till about three years of age. In Uruguay, for example, Hormaeche (1940) recorded a case-fatality rate in infants under one year of age of 45 per cent., and Blacklock and Guthrie (1937) in Glasgow of 59 per cent. These figures relate to the severer cases that were admitted to hospital, and are not truly representative. For the population as a whole the case-fatality rate in frank cases of the disease in Denmark, Great Britain and the United States is probably about 2 per cent. (Bojlén 1934, Scott 1938, Weil 1943). In temperate zones the disease is commoner in the summer months, but the seasonal difference in incidence is relatively small. In sub-tropical and tropical countries, however, the effect of season is more striking. According to Rogers (1913), for example, bacillary dysentery in India is at a minimum in the cold months of January and February. With the onset of the hot weather in March there is a small rise, followed, however, by a fall during the very hot months of May and June. The maximum increase follows closely the beginning of the heavy monsoon rains in July, and the incidence reaches its highest point in August and September. With the cessation of the rains late in October and the fall of temperature, the incidence steadily declines.

It is of interest to note that the months when dysentery is most common are also the months when flies are most abundant. In this country Graham-Smith (1911–12) showed that non-lactose-fermenting Gram-negative bacilli could often be isolated from flies during the summer months when diarrhœa was prevalent, and that these insects could contaminate food over which they walked.

Working in Fiji, Manson-Bahr (see Bahr 1912) likewise obtained evidence that infection was partly carried by the house fly. The fly population was at its maximum when dysentery was most prevalent. Ample opportunity existed for con-

tamination of the food ; and *Sh. shigæ* was actually isolated from the lower intestinal tract of two flies caught on the bed of a patient suffering from acute dysentery. This suggestion was confirmed by the careful work of Taylor (1919) during the first world war. In the Salonika Expeditionary Force the maximum incidence of dysentery occurred when flies were most abundant. The conditions of temperature and humidity most favourable for fly breeding were present between the middle of April and the middle of June, and again between the middle of September and the end of October. Corresponding to this, the peak of the dysentery curve was reached at the end of May and at the end of October. During the hot dry weather of July, August, and early September, both the fly prevalence and the dysentery incidence curves fell practically to zero (Fig. 284). Experiments made

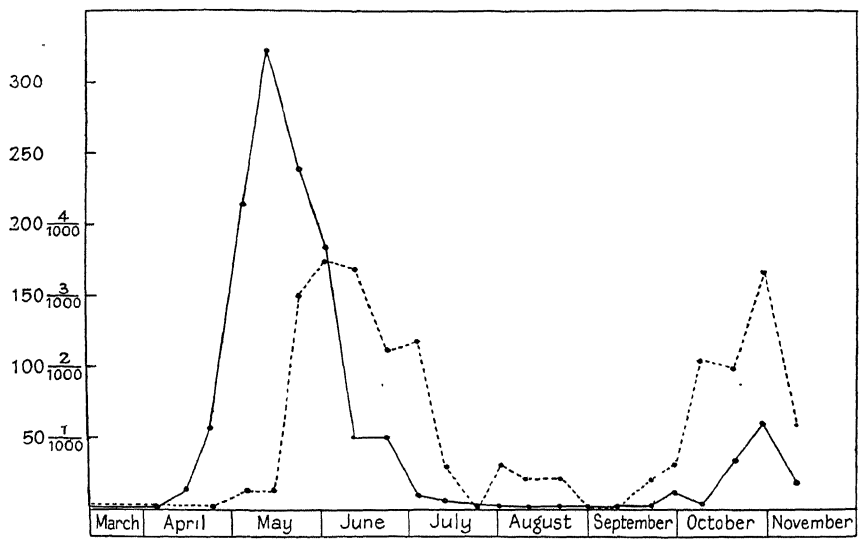

FIG. 284.

Showing the relationship between the prevalence of flies and the incidence of dysentery in the Salonika Expeditionary Force.

Continuous curve = Number of flies trapped *per diem*.
Interrupted curve = Incidence of dysentery cases per 1,000 *per diem*.
(After Taylor.)

to test the ability of flies to carry dysentery bacilli showed that these insects, after feeding on milk cultures or on dysenteric fæces, might remain infective for 24 hours. Of 1,670 flies caught under natural conditions, 1 from a hospital kitchen was carrying *Sh. shigæ*, and 8 were carrying Flexner's bacillus. Manson-Bahr (1919) likewise isolated *Sh. shigæ* from the lower intestine of flies in Palestine. It is doubtful whether under the modern sanitary conditions of Western civilization flies play more than a small part in the transmission of either the epidemic or the endemic disease. In the East and Middle East, however, as has been shown again in the experience of the second world war, fly-borne infection is of major importance (Fairley and Boyd 1943); and even in the United States it is not unknown under military conditions (Kuhns and Anderson 1944). Though dysentery bacilli may be found occasionally in the intestinal contents of these insects,

they do not appear to survive for more than a few days. The probability is that flies act mainly by carrying infective material on their feet rather than in their intestine.

Epidemic infection may result from the contamination of milk or of ice-cream; several well-authenticated outbreaks due to these vehicles have now been recorded in different countries. Under exceptional conditions the disease may be water-borne; but though one large outbreak in Japan due to an aberrant dysentery bacillus affecting 11,000 persons and causing 500 deaths (Report 1938), another large outbreak in Kansas due to *Sh. flexneri* affecting 3,000 persons (Kinnaman and Beelman 1944), and a smaller outbreak in this country affecting about 400 persons, in which *Sh. sonnei* was isolated from the water itself (Green and Macleod 1943), apparently arose in this way, the evidence does not suggest that epidemic disease is often determined by such means. In Java, however, where peculiar conditions prevail, bacillary dysentery is said to be predominantly a water-borne disease (Fairley and Boyd 1943). Food, especially of the ready cooked type, probably constitutes an important means of transmission.

Infection is derived as a rule from cases, particularly ambulant cases, of the disease, from healthy convalescents, from symptomless carriers—usually temporary—and probably far less often, except in mental institutions, from chronic carriers. The organisms, which are excreted in the fæces, may gain access to food through the imperfectly cleansed fingers of the patient or carrier; or they may pass from one person to another by contact with inanimate articles such as seats, door handles, and water-flushing devices in lavatories, bed-pans and washing bowls in hospital wards, pencils and books in schools, and crockery and glasses in restaurants. There are in fact so many ways in which infection may spread that, once it is introduced into nurseries or children's wards in hospitals, it is often extremely difficult to eradicate.

Bacillary dysentery varies greatly in its clinical manifestations and in its severity. In every outbreak there are a number of cases of simple diarrhœa, which are nevertheless caused by the dysentery bacillus. Entirely symptomless carriers are not uncommon, and in endemic areas may constitute a considerable proportion of those found to be infected (Watt and Hardy 1945). Even though the disease is often fatal in infants and very young children, it may be extremely mild and give rise to no more than a trivial disturbance of the bowel disappearing within 24 hours (Report 1943*a*). Occasionally food-borne outbreaks, particularly of the Sonne type, are characterized by acute gastro-enteritis rather than by true dysentery (Rohleder 1938, Report 1942*a*). A very small number of cases of dysentery that recover, about 2 to 3 per cent. according to Bojlén (1934), are said to suffer from chronic colitis. Among the few complications that may occur conjunctivitis is to be looked for about the tenth day of the disease and iritis during the second week; arthritis and neuritis are sometimes met with (Manson-Bahr 1942).

Asylum Dysentery.—Asylum dysentery is a particular form of the endemic disease occurring in a closed community. It is to Kruse (1901) that its recognition as an infectious disease was mainly due. In this country Mott (1901–02) made a careful study of the condition from its clinical and epidemiological aspects. More recently Bojlén (1934) carried out an extensive series of observations in Denmark. He found that, in contrast to endemic dysentery in the general population, asylum dysentery is characterized by a high case mortality, varying from about 10 to 20 per cent. Relapses, and probably re-infections, are very common,

and as many as 50 per cent. of the inmates may suffer from chronic dysentery. Persistent carriers are met with, and together with the numerous patients suffering or recovering from dysentery, they provide a continual source of infective material which is responsible for the further propagation of the disease. Spread of infection by carriers is of course rendered particularly easy owing to the low standard of personal hygiene among the insane.

Bacteriological Findings in Different Epidemics.—One of the striking features of the bacteriology of dysentery is that in any large epidemic it is almost invariable to find bacilli of more than one type. A pure *shigæ* or a pure *flexneri* epidemic on a large scale appears to be a rarity, though in small outbreaks a single type may alone be isolated (Kruse *et al.* 1907). Not only so, but in any large outbreak, besides the well-defined Shiga and Flexner bacilli, it is usual to isolate a number of other organisms. In the past these have been referred to as para-Shiga, in-agglutinable Flexner, or more generally para-dysentery bacilli. Our increasing knowledge has served to classify many of these organisms into Schmitz, Sonne, Boyd and Newcastle types. There remain, however, a number of strains whose exact classification is at present doubtful, and whose rôle in the causation of dysentery still awaits elucidation. Where the disease is endemic, only one or two types may be concerned, and in institutions only a single type may be found.

In different epidemics, in different countries, and at different times, the proportion of cases due to different bacillary types varies considerably; and even in the same epidemic the results of different observers may show a marked dissimilarity in this respect. In the British Salonika Force, Dudgeon (1919) and his co-workers obtained the following distribution of organisms in bacteriologically positive cases of dysentery (Table 139):

TABLE 139

	No. of Cases.	Percentage.
Sh. shigæ	335	38·3
Sh. flexneri Y	503	57·6
Other Types	36	4·1

That is to say, Flexner's bacillus was half as common again as *Sh. shigæ*. But Graham (1918) and his co-workers, who investigated 2,500 cases of dysentery and diarrhœa in the British Salonika Force at much the same time—June, 1916, to the end of 1917—found that of the severe and moderately severe bacillary dysenteries 75 per cent. were due to *Sh. shigæ* and only 25 per cent. to *Sh. flexneri Y*, whereas of the mild bacillary dysenteries 75 per cent. were due to *Sh. flexneri Y* and only 25 per cent. to *Sh. shigæ*.

The figures given by Boyd (1936) in India are more complete (Table 140). They show that just over half the strains isolated were of the classical Flexner type, and that about 13 per cent. belonged to newly recognized Flexner or Boyd types; Shiga's bacillus constituted about 15 per cent., Schmitz's bacillus 5 per cent. and Sonne's bacillus 9 per cent. of the total strains studied.

In the United States Shiga's bacillus seems to be uncommon. Hardy, Watt, Kolodny and DeCapito (1940), who isolated 2081 strains of dysentery bacilli from cases of diarrhœa and dysentery in New Mexico during the years 1936, 1937, and 1938, did not meet with it once. They identified 65·0 per cent. of their strains

as *Sh. flexneri*, 19·1 per cent. as *Sh. sonnei*, and 15·9 per cent. as *Sh. newcastle*. Shiga's bacillus is, in fact, seldom met with except in tropical countries and East Asia (Weil 1943).

TABLE 140

TYPES OF DYSENTERY BACILLI ISOLATED IN INDIA 1932 TO 1934 (MODIFIED FROM BOYD 1936)

	No. of Strains.	Per cent.
Sh. shigæ	820	14·94
Sh. schmitzi	296	5·39
Sh. newcastle (Type 88)	240	4·37
Sh. flexneri Types V, W, X, Y, Z	2,888	52·61
„ „ Type 103	135	2·46
„ „ Type P119	100	1·82
Sh. boyd Type 170	134	2·44
„ „ Type P288	26	0·47
„ „ Type P274	47	0·86
„ „ Type D1	41	0·75
„ „ Type D19	5	0·09
Inagglutinable mannitol fermenters	57	1·04
Mannitol fermenters not fully investigated	95	1·73
Sh. sonnei	508	9·25
Inagglutinable lactose and sucrose fermenters	97	1·77
	5,489	99·99

Clinically the disease due to Shiga's bacillus is much more severe than that due to Flexner's; as well as the abdominal pain, diarrhœa and tenesmus, there is often a profound toxæmia ending in collapse. Complications such as arthritis (Graham 1919, Report 1919) and iridocyclitis, when they do occur, are almost invariably associated with the Shiga type of infection. Moreover, recovery from dysentery due to *Sh. shigæ* is a slow process; frequently the patients remain debilitated for months, and on attempting to resume work are liable to relapse (Fletcher and Mackinnon 1919). This corresponds with the result of animal experiments, which show that Shiga's bacillus is much the more toxic organism of the two.

Besides the historically well-known Shiga and Flexner types, a number of other types have been recognized of late years. Some of these play a very important part in the causation of dysentery, particularly of the endemic and institutional variety, and require attention.

Schmitz's Bacillus.—This was described by Schmitz (1917), and called *B. ambiguus* by Andrewes (1918). It was first encountered (with the possible exception of an American outbreak, see Park and Carey 1903) as the cause of an epidemic of dysentery in a Roumanian Prisoners of War Camp. The morbidity rate was high —10 per cent.—but the deaths were few. The bacillus, which, it will be remembered, differs from *Sh. shigæ* in producing indole, was isolated from a number of the patients. It was agglutinated by their serum to a titre of 1/500 to 1/1,000; Shiga's bacillus was likewise agglutinated to much the same titre, but Flexner's bacillus only to between 1/200 and 1/500. Apparently the bacillus was able to give rise to the production of group agglutinins, which were especially active towards *Sh. shigæ*. Incidentally it is interesting to remark that the epidemic occurred in the depth of the very severe winter of 1916–17, and indeed reached its

maximum in January of the latter year. There is little doubt from Schmitz's account that the insanitary conditions prevailing in the camp were sufficient to explain the spread of the disease. This bacillus has now been found in other countries (see Mandry 1935, Boyd 1935, 1936). Of late years it has been reported mainly from institutions, especially for mental patients. Schleifstein and Coleman (1937), for example, recorded an outbreak affecting 200 persons in a New York State institution; and in this country reports of cases in mental institutions have come from Evans (1938) in Wales, from Knox in Leicester (Report 1942c), and from Shera (1943) in Eastbourne. It is rarely responsible for more than a minority of cases in any given area.

Para-Shiga Bacilli.—Attention was drawn by Dudgeon and Urquhart (1919) to the occurrence among dysentery cases in Macedonia of non-mannitol-fermenting bacilli that failed to agglutinate with a Shiga antiserum. Since then, numerous authors have made similar observations, such as Large and Sankaran (1934) and Sachs (1943) in India, Ali (1938) in Egypt, and Hazen (1938) in the United States. Some of these so-called para-Shiga bacilli produce indole, others do not. They differ also in arabinose fermentation and in certain other ways. Sachs (1943) recognized eight different types, all antigenically distinct. At Quetta, where he looked for them carefully, they constituted 7 per cent. of the dysentery strains isolated. They were found mainly in the first three days of the disease, and were absent from control patients. As a rule agglutinins appeared in the serum of the patient, reaching a titre of 1/250 or 1/500; no agglutinins were found in a series of 200 Wassermann sera examined. Of the para-Shiga strains isolated, 93 per cent. came from cases of acute dysentery, in which no other type of dysentery bacillus could be demonstrated. In view of these observations, and of others so far unpublished, there is little doubt that para-Shiga bacilli may give rise to clinical dysentery.

Sonne's Bacillus.—This is a more important organism. Though it had undoubtedly been previously observed in the United States and Germany, it was Sonne's description in 1915 that drew serious attention to it. From a number of sporadic cases of dysentery in Denmark Sonne cultivated a bacillus differing from *Sh. flexneri* in its late fermentation of lactose, in its marked production of acid in litmus milk during the second week of incubation, and in its different serological reactions. In an investigation of dysentery in Norway, Thjøtta (1919) found that 25 out of 65 strains isolated conformed to the Sonne type. More recent work in Denmark (Bojlén 1934) has shown that *Sh. sonnei* is as common as *Sh. flexneri* in the causation of endemic and institutional dysentery. In this country the organism has been often encountered (see Channon 1926, Kerrin and Cruickshank 1926, Fyfe 1927, Hay 1930, Cann and de Navasquez 1931, MacGill and Downie 1932, Pickles 1932, Nabarro and Signy 1932, Laws 1936, Carter 1937, Thornton and Darmady 1938). It seems to be very common in the United States and Canada (see Johnston and Brown 1930, Nelson 1930, Leahy 1931, Felsen and Osofsky 1934, Weil 1943), and has been observed in several other parts of the world. It is most frequently met with in endemic dysentery, particularly in asylums, children's hospitals, and nurses' homes. In infants it may give rise to an acute toxic form of dysentery, which in Japan is known as *Ekiri*. The disease may, however, occur in epidemic form, and several milk-borne outbreaks have been described (see Sylvest 1933, Bojlén 1934, Felsen and Osofsky 1934, Bowes 1938, Faulds 1942, 1943). Leuchs and Heim (1930) report an outbreak involving 51

persons due to infected cheese. Clinically, Sonne dysentery is said by some observers to be less severe than Flexner dysentery, but Bojlén (1934) disputes this. Mild and atypical cases of the disease are common in any reasonably large outbreak. As has already been mentioned, Sonne's bacillus often gives rise to acute gastro-enteritis rather than to dysentery proper. Rohleder (1938), who analysed 118 cases in which this bacillus was demonstrated, found that 72 of them had run a clinical course indistinguishable from that of a simple gastro-enteritis. Bacteriologically, the organisms are found in the fæces, and occasionally in the urine (Rohleder 1938); agglutinins are often demonstrable in the blood serum of patients suffering or convalescent from the acute disease. The closely related organism, *Sh. dispar*, has so far not been definitely incriminated as a cause of dysentery, but further observations are required (see Forsyth 1933). The fact that some indole-positive strains were isolated by Felsen and Osofsky (1934) and Beck and Buckle (1939) from hospital outbreaks of dysentery suggests that this organism cannot be dismissed as a possible cause of the disease.

Newcastle Bacillus.—This organism was first recognized as a cause of dysentery by Clayton and Warren (1929*a*, *b*) in Newcastle. Downie, Wade and Young (1933) in Manchester described a similar organism, differing in the fermentation of mannitol; and Boyd (1936) in India described under the term Type 88 another organism that fermented mannitol but produced no trace of gas in glucose. Whitehead and Scott (1934) pointed out the relationship between these three organisms. The Newcastle bacillus, in one or other of its variant forms, has now been isolated from many parts of the world. In the series of 2,081 strains of dysentery bacilli studied by Hardy, Watts, Kolodny and DeCapito (1940) in New Mexico, it constituted no less than 15·9 per cent. of the total.

Shigella flexneri Types 103 and P119.—Type 103 formed 4·1 per cent. and P119 2·7 per cent. of 4,856 strains of mannitol-fermenting dysentery bacilli studied by Boyd (1938) in India during the years 1932 to 1934. From the evidence presented by Boyd (1931, 1936) there seems little doubt that both these organisms, which are antigenically related to *Sh. flexneri*, are capable of giving rise to dysentery.

Shigella boyd Types 170, P274, P288, D1.—Types 170, P288, and D1 are believed by Boyd (1939–40) to be responsible for some cases of dysentery. In India they comprised 3·9, 1·3, and 1·4 per cent. respectively of the series of 4,856 strains alluded to above. P274, whose pathogenicity seems to have been established by Rothstadt, Fenner and Baker (1942), comprised 1·5 per cent.

Shigella alkalescens.—That this organism is occasionally pathogenic to man there seems little doubt. It was isolated from the blood stream of a woman suffering from puerperal fever (Smith and Fraser 1928), and was encountered in an institutional outbreak of food poisoning (Welch and Mickle 1934). It has been cultured from the fæces of sporadic cases of dysentery, chronic enteritis, and diarrhœa (see Brown and Anderson 1936); but it seems to be found most frequently in infections of the urinary tract (Snyder and Hanner 1937, Neter and Heide 1940). Like many other non-lactose fermenters it is commoner in the inflamed than in the normal intestine, and its mere presence cannot therefore be regarded as establishing its pathogenicity.

The rôle of Morgan's No. 1 bacillus—*Proteus morgani*—is likewise doubtful. Douglas and Colebrook (1917) found it in 29 per cent. of patients who had contracted

dysentery in Gallipoli, while Candler and Dean (1911) isolated it from 5 out of 16 patients suffering from asylum dysentery. It seems to be an organism that is capable of multiplying in the intestine under suitable conditions, but it can hardly be ranked along with the Shiga, Flexner, and Sonne types as a primary cause of dysentery.

Dysentery Carriers.—Patients recovering from an acute attack of dysentery may continue to excrete the bacilli in their stools. Generally this excretion lasts for only a week or so, but a small proportion become persistent carriers.

Fletcher and Mackinnon (1919), who during the war of 1914–18 had unrivalled opportunities for studying the carrier condition in a depot for dysentery convalescents, found that of 935 patients 71 or 7·59 per cent. were carriers, and that 26 or 2·78 per cent. were persistent carriers. (They defined " persistent carrier " as one who carried the bacilli for more than 3 months after the beginning of the disease.) Of the 71 carriers 58 were carriers of Flexner's and 13 of Shiga's bacillus. Between these two classes there were striking differences. All the *shigæ* carriers belonged to the persistent group, whereas only 13 of the *flexneri* carriers were persistent excreters. The *shigæ* carriers excreted the bacilli with greater constancy than did the *flexneri* carriers; thus out of 469 samples of fæces from *shigæ* carriers the bacillus was isolated 207 times, or once in every 2·26 specimens; whereas of 1,803 samples from *flexneri* carriers the bacillus was found only 330 times, or once in every 5·46 specimens. The *flexneri* carriers had a tendency to be intermittent; the bacillus was excreted for one or two days in succession, and then not again for a month or more; it was then excreted once more, only to disappear again after a few days. Even more striking was the clinical difference between the two series. The *shigæ* carriers looked ill and suffered from chronic dysentery and extreme mental depression; the *flexneri* carriers, on the other hand, were in moderately good health and were comparatively cheerful. This is to be attributed in part at least to the frequent relapses to which the *shigæ* carriers were subject; no sooner had their diarrhœa ceased and their general condition improved, than the slightest dietetic indiscretion or resumption of exercise or work brought on again an acute attack of the disease.

The conclusions to be drawn from these observations are that dysentery due to *Sh. shigæ* is altogether a more serious condition than that due to *Sh. flexneri*, and that its liability to become chronic renders it a cause of prolonged invalidism. Both classes of carriers are, however, a danger to the community, and every practicable step should be taken to avoid their spreading the disease.

Studying institutional dysentery in Denmark due to *Sh. flexneri* and *Sh. sonnei*, Bojlén (1934) was struck by the frequency of persistent carriers. Some patients, whose stools were systematically examined, were found to excrete the bacilli for years. The experience of most workers, however, shows that chronic carriers—that is, those who excrete the organism for a year or more—are infrequent, and therefore play but a small part in the spread of the disease, except perhaps in mental institutions.

It is sometimes stated that there are no healthy carriers of dysentery bacilli, and that all those who excrete the organism are suffering from chronic dysenteric lesions (see Scott 1938). The evidence in favour of this view is far from convincing. Several workers have demonstrated the presence of *Sh. flexneri*, *Sh. sonnei*, *Sh. schmitzi*, and even *Sh. shigæ* in completely symptomless carriers (see Report 1942*b*, *d*, Weil 1943). It is possible that before the introduction of desoxycholate citrate medium, cultures were successful only from heavily infected persons; but now that even small numbers of dysentery bacilli may be demonstrated, the existence of perfectly healthy carriers is no longer in doubt. Hardy, Watt and

DeCapito (1942), for example, found that in an endemic area as many as 3·8 per cent. of persons who gave no history of illness during the preceding year were "passive carriers" of the dysentery bacillus. Doubtless they had been in contact with other carriers or cases, and had become infected without developing the disease.

The introduction of S.S. and desoxycholate media has also led us to modify somewhat our ideas on intermittency of excretion. Even so, it is not uncommon to observe intermittency in convalescents and carriers, though less often than formerly (see Cruickshank and Swyer 1940, Report 1942*e*). The apparent duration of excretion has been extended by the use of these media. Most workers would have been prepared to accept Fletcher and McKinnon's (1919) findings that not more than 2 to 3 per cent. of convalescents carried the bacillus for over three months. Watt, Hardy and DeCapito (1942), however, working with S.S. and with desoxycholate citrate media, found that 11 per cent. of Flexner, 10 per cent. of Newcastle, and 7 per cent. of Sonne carriers excreted the bacillus for over ten weeks.

In conclusion it is worth while comparing dysentery with other enteric infections, notably typhoid. Dysentery has a short incubation period, about 48 hours as a rule. It is essentially a local disease ; the bacilli remain confined to the intestine and to the mesenteric glands ; they do not invade the blood stream, nor are they, except occasionally, found in the spleen or liver. In this respect dysentery—of the *shigæ* type—has been compared to diphtheria ; the bacilli produce a necrosis of the intestinal mucosa, often with pseudo-membrane formation, and their toxic products are absorbed, giving rise to profound systemic disturbance. The disease may also run a chronic course. Typhoid fever, on the other hand, has a long incubation period—up to 21 days ; it is primarily a septicæmic disease with secondary localization in the intestine ; the bacilli do not produce a soluble exotoxin ; and the disease has little tendency to become chronic.

Laboratory Infection in Man.—It has been pointed out in Chapter 29 that, with the possible exception of monkeys, dysentery cannot be reproduced in laboratory animals. There are, however, a few definite cases recorded in the literature of experimental infection in human beings. Kruse (1901) mentions the case of Dr. Stöcker, an assistant in his laboratory at Bonn, who apparently infected himself while working with cultures of Shiga's bacillus. He suffered from a mild attack of the disease ; the bacilli were isolated from his stools ; and a typical rise and subsequent fall were observed in his blood agglutinins. For several years previously there had been no dysentery in the town. Flexner (1900*b*) likewise records the case of a laboratory assistant at Baltimore, who aspirated a fluid culture of the Flexner Manila strain into his mouth. He spat it out and rinsed his mouth with weak phenol, but within 48 hours he had severe diarrhœa, pain, and tenesmus, with blood and mucus in his stools. Unfortunately no cultures were made.

Diagnosis.

Blood and urine cultures are almost invariably sterile. In the bacteriological diagnosis of dysentery most stress should be laid on the isolation of the specific organism from the fæces, less on the presence of agglutinins in the patient's serum. The fæces should be examined as early as possible in the disease. The highest percentage of positive results is obtained from blood-and-mucus stools (Table 141).

TABLE 141

SHOWING PROPORTION OF ISOLATIONS OF DYSENTERY BACILLI FROM DIFFERENT TYPES OF FÆCES (Report 1919).

Total number of cases examined = 3,125.

	Blood and Mucus.	Diarrhœal Stools plus Mucus.	Diarrhœal Stools.
Total Number Bacteriologically examined.	1,103	741	1,281
Positive	664 or 60·2%	160 or 21·6%	50 or 3·9%
Negative	439 or 39·8%	581 or 78·4%	1,231 or 96·1%

The best results are obtained when the blood and mucus are examined within an hour of being passed, before other organisms have had time to proliferate. If this is impossible, the mucus or fæces should be collected into a buffered 30 per cent. glycerol saline solution, such as that described by Sachs (1939), which prevents the dysentery bacilli being destroyed by the acid produced during the growth of other organisms. Rectal swabs are often of value in acute cases, or when special care has to be exercised to avoid substitution, or, in hospitals, in order to avoid contamination of the sample through imperfectly sterilized bed-pans.

Microscopical examination of the mucus in the early stage of acute bacillary dysentery shows an extreme degree of cellularity, 90 per cent. or more of the cells, apart from red blood corpuscles, being polymorphonuclears. In the later stages the number of cells decreases, the pus cells become degenerate and proportionately fewer, the red blood corpuscles are scanty or absent, mononuclear cells increase, and the exudate, in coming to resemble that found in amœbic dysentery, loses its diagnostic significance.

Cultures should be made, preferably from washed flakes of mucus, on Leifson's (1935) desoxycholate citrate agar or on the so-called S.S. medium, both of which are very much superior, especially in the examination of convalescents and contacts, to MacConkey's or Endo's medium (see Hardy *et al.* 1939, 1942, Hynes 1942, Pot 1942, Report 1942*f*). The brilliant green method, which is of such value in the isolation of *Salmonella*, is of no help in the cultivation of dysentery bacilli, since these organisms are as susceptible to the dye as *Bact. coli* (Krumwiede and Pratt 1914, Myers and Koser 1932). Colonies should be picked off into lactose broth, put through the sugars, and tested by the tube or the slide method against specific agglutinating sera of the types most likely to be met with in the area concerned. Slide agglutination must be used with care, particularly for colonies off selective media, since non-specific results are common. Shiga's bacillus on first isolation may be poorly agglutinable; heating for 1 hour at 60° C. is said to improve it (Schütze 1944). It should also be remembered that Flexner's bacillus may contain somatic antigens of the *Salmonella* group. A motility test, preferably at 22° C., should never be omitted (Braun and Weil 1928).

Agglutinins appear in the patient's serum about the 6th to the 12th day, but sometimes not till later, or not at all. The serum should be tested against standard suspensions of the common types of dysentery bacilli. The tubes are best incubated in a water-bath at 50° C. for 4 to 6 hours, left overnight at room temperature, and read finally the next morning.

Much less attention can be paid to the presence of serum agglutinins in the diagnosis of dysentery than in that of enteric fever. This is partly because normal

human serum may contain agglutinins for dysentery bacilli, and partly because the group agglutinins may be so prominent as to render the diagnosis of the type of bacillus almost impossible. The value of the test depends to a considerable extent on the frequency distribution of normal agglutinins in the population. In endemic areas and in mental institutions in which dysentery is common, interpretation of low serum agglutinin titres is very difficult and often impossible (see Dudgeon 1919). On the other hand, in areas in which dysentery is uncommon, and especially in children, whose serum is usually devoid of normal agglutinins, the test may be of value. Under these conditions a titre of 1/25 or over to *Sh. shigæ*, *Sh. schmitzi*, or *Sh. sonnei*, and a titre of 1/100 or over to *Sh. flexneri* is highly suggestive of active infection. Except to *Sh. flexneri*, the agglutinin titre seldom rises high, and often declines in early convalescence. In Sonne infections only about 60 per cent., as a rule, of patients develop serum agglutinins (Smith and Fraser 1930, Johnston and Brown 1930, Nabarro and Signy 1932, Laws 1936, Cruickshank and Swyer 1940), so that, while a positive result may be diagnostic, a negative result does not exclude the presence of active disease. In chronic cases agglutinins may persist for a long time.

Diagnosis at autopsy should be made by taking cultures from the mucosa and submucosa of the affected part of the intestine, and from the corresponding mesenteric glands. (For a fuller description of the diagnosis of bacillary dysentery see Report 1920.)

Prophylaxis, Vaccination and Serum Treatment.

Prophylaxis.—The general prophylaxis of bacillary dysentery is so similar to that of typhoid fever that there is no need to consider it in detail. Particular attention should be paid to the extermination of flies, and to the protection of food from both flies and dust. Persons who have had dysentery should not be permitted to act as cooks, or to have anything to do with the preparation of food.

If an outbreak of dysentery occurs in an institution, attention should be concentrated on the mode of preparation and distribution of food and on the prevention of direct and indirect cross-infection. The kitchen staff and all those in any way concerned in the handling of food should be carefully questioned for a history of current or recent intestinal disturbance, and should be instructed to report directly to an officer who is solely responsible for the control of the outbreak. Intensive examination of the food personnel for the presence of carriers, some of whom may be entirely symptomless, is to be recommended provided adequate laboratory facilities are available. Repeated samples of stools are usually required in order to detect fresh cases of infection and intermittent excreters. Bacteriological examination may be extended to the whole institution, but as a rule it is sufficient to restrict this to the food personnel and to segregate all other persons, whether staff or patients, who have a history of diarrhœa, dysentery, or chronic colitis (see Bojlén 1934). In hospital wards, however, bacteriological control is often necessary if infection is to be eradicated in the shortest possible time. Particular attention should be paid to the disinfection of lavatory seats, door handles, and water-flushing devices. Bed-pans are a fertile source of cross-infection in wards, and should be sterilized by boiling, steaming, or immersion in disinfectant after the contents have been evacuated. Under field conditions the fæces themselves must be burnt or disinfected (see Fairley and Boyd 1943), but in institutions with a satisfactory conservancy system this is seldom required. Though it

often presents practical difficulties, the rule should be enforced that no nurse handling bed-pans should have anything to do with the preparation or distribution of food. Each patient should have his own crockery and feeding utensils, which should be disinfected after use. All persons in the institution must be instructed to wash their hands thoroughly in a disinfectant solution, such as one containing 0·1–0·2 per cent. of active chlorine, after defæcation. In mental hospitals convalescent and chronic carriers probably play a large part in perpetuation of the infection, and must be sought for and suitably controlled.

Vaccination.—The value of vaccination in the prophylaxis of dysentery is still undecided. There are two main difficulties. Firstly, there are so many different types of dysentery bacilli that any vaccine to be effective would have to be polyvalent. Secondly, owing to the great toxicity of Shiga's bacillus, the preparation of a suitable vaccine has so far proved impracticable.

Numerous attempts have been made to overcome this latter difficulty by modifying the toxicity through the addition of tricresol (Gay 1902), eusol (Dean and Adamson 1916), hydrogen peroxide (Dean and Adamson 1916), formalin (Dumas, Ramon and Bilal 1926), or soft X-rays (Moore and Kersten 1936). Shiga (1903) advocated the use of a sero-vaccine, the first dose of which was followed in 4 days by an inoculation of bacilli alone. Antibodies were demonstrable in the blood of inoculated persons 3 to 4 weeks later. This method was used on about 10,000 persons in Japan during the years 1898–1900, and is said to have had little effect on the morbidity, but to have decreased the mortality considerably. Unfortunately Shiga gave no exact figures of the results. Olitsky (1918) has suggested the use of a lipo-vaccine consisting of heat-killed bacilli suspended in neutral almond oil, on the principle that, owing to slower absorption of the toxin, the patient's reaction should be correspondingly less. Iguchi, Ohstubo and Eguchi (1933) have tried oral vaccination with apparently satisfactory results; these, however, still await confirmation. More recently Boivin and Mesrobeanu (1938) have recommended the use of a glycolipoid antigen extracted from Shiga's bacillus, and Morgan and Schütze (1943) a phenol extract of the somatic antigen. No satisfactory or convincing evidence has yet been brought to show that in practice any of these vaccines is able to contribute significantly to the prophylaxis of Shiga dysentery. Formol toxoid is said by O'Brien (1939–40) to be a good antigen for horses, but it seems doubtful from the work of Steabben (1943) whether it could be relied on to protect against infection with living bacilli.

The difficulty of preparing a polyvalent vaccine against 6 or 12 types of dysentery bacilli and ensuring a satisfactory antigenic contribution from each of them is obviously considerable. Scott (1938) suggests for institutional use in this country a vaccine containing 150 million per ml. of each of the five common serological types of Flexner bacilli together with the same number of Newcastle and Sonne bacilli. He advises a dosage of 0·5 to 1 ml. according to age, sex, and physical strength, the vaccine being given on admission and repeated annually. Though private reports are often favourable, it must be remembered that rigidly controlled observations on alternate vaccinated and control patients are seldom made; and until more information is available it is probably wise to suspend judgment on the prophylactic value of dysentery vaccines.

Serotherapy.—Todd (1904) working in London, and Rosenthal (1903, 1904) working in Moscow, showed independently that the soluble toxin contained in cultures of *Sh. shigæ* was able to give rise on injection into animals to a true neutralizing antitoxin. Todd found that the serum had definite protective properties; if it was injected intravenously into a rabbit, it protected the animal

against a lethal dose of toxin or of dead bacilli, given simultaneously or half an hour later. A horse serum that he prepared contained sufficient antitoxin per ml. to neutralize 20,000 lethal doses of toxin for a rabbit. The union of toxin and antitoxin appears to take place in constant proportion (Pfeiffer and Ungermann 1909, Kolle *et al.* 1924).

Antiserum is prepared by the intravenous injection of horses, first with heat-killed and later with living bacilli (Flexner and Amoss 1915). More recently dysentery anatoxin has been used for the production of serum (Dumas *et al.* 1926).

The titration of the serum is best carried out on the mouse, using intravenous inoculation (Kolle *et al.* 1924, Sudmersen *et al.* 1924). O'Brien and Runge (1925) suggested as a provisional standard that the unit of antitoxin should be that amount of serum which would neutralize the test dose—0·2 mgm.—of a standard toxin; the test dose was approximately 10 lethal doses for the mouse. An improved method was described by Blake and Okell (1929), which according to Trevan (1929) leads to an increased accuracy in titration. Zozaya (1932) has used the polysaccharide precipitation test for the antibacterial standardization of serum, but Kurauchi and Nagata (1935) have reported unfavourably on this method.

Under the Therapeutic Substances Act one unit of Shiga antiserum is contained in 1/200 ml. of a 1 per cent. solution of a standard dry (Copenhagen) serum.

In practice the results of serum treatment are not very convincing. Shiga (1901), in Japan, tested the therapeutic effect of an antidysentery serum, the method of preparation of which is not recorded; from his report we have constructed the following table (Table 142).

TABLE 142

SHOWING MORTALITY OF PATIENTS IN HOSPITAL TREATED WITH MEDICINE ALONE OR WITH SERUM.

Year.	Hospital.	Mode of Treatment.	No. Treated.	Died.	Mortality.
					Per cent.
1895–99 . . .	Municipal	Medicine	2,565	929	36·2
1899	,,	Serum	88	11	12·5
1897	Infectious	Medicine	34	8	23·5
1898–1900 . .	,,	Serum	210	20	9·5

Unfortunately the figures of the serum-treated cases are few; moreover the comparison, so far as individual hospitals are concerned, has been made between the mortality of cases treated with serum in one year and that of cases treated without serum in previous years. Shiga concludes, however, that serum treatment reduced the mortality to about one-third of its former value. (For records of results obtained by other authors previous to 1907 see Deane 1907.)

During the first world war Graham (1918) treated a number of cases occurring in the British Salonika Force with a serum prepared against both Shiga and Flexner strains, and recorded favourable results in the relief of abdominal pain and tenesmus. During the second world war Fairley and Boyd (1943) had the opportunity of trying the effect of highly potent protein-digested anti-shigæ serum containing 20,000 I.U. per ml. Its use was restricted to proved Shiga cases. It was given intravenously in a dose of 5 to 10 ml., and repeated daily when thought advisable.

No serum reactions were observed in a series of over thirty cases. Though clinical improvement sometimes followed, it was often only transient. The authors formed the opinion that the serum was of temporary benefit by neutralizing toxin, but failed to modify the course of the disease on account of its lack of antibacterial activity. This view is largely borne out by the animal experiments of Felsen and Osofsky (1938), O'Brien (1939–40), and Steabben (1943). Fairley and Boyd would restrict the use of Shiga antiserum to fulminating or severely toxic cases immediately on admission to hospital, and to cases in which chemotherapeutic treatment has failed. The dosage should be not less than 200,000 I.U. intravenously, repeated in 12 hours if necessary.

On the whole, therefore, we may conclude that treatment with antitoxic serum to the Shiga bacillus is of limited and transient value. Its usefulness in practice is further curtailed by the inability to decide by clinical inspection alone whether a given patient is infected with the Shiga bacillus, or with some other type of dysentery bacillus. No evidence is available to show that a serum prepared against either the Flexner or the Sonne bacillus is of any therapeutic value (O'Brien 1939–40).

Treatment with *bacteriophage* has been tried. Some workers, such as Compton (1942), are convinced of its efficacy, but the findings are not sufficiently conclusive to demand detailed attention (see Riding 1930, Weil 1943, Fairley and Boyd 1943, Boyd and Portnoy 1944).

Chemotherapy.—Treatment of dysentery cases with drugs of the sulphonamide group is now being extensively used, and, though caution is necessary in interpreting the results (see Boland 1943), there is a general consensus of opinion that it constitutes a valuable form of therapy. There is still no unanimity on the best form of drug to employ. Sulphapyridine has been favourably reported on by Paulley (1942) and Swyer (1943), but most workers prefer sulphaguanidine on account of its lower toxicity and its lesser tendency to give rise to renal deposits. Fairley and Boyd (1943) recommend for acute cases an initial dose of 0·1 gm. per kilo of sulphaguanidine, a maintenance dose of 0·05 gm. per kilo 4-hourly so long as the number of stools exceeds five a day, and a further maintenance dose of 0·05 gm. per kilo. every 8 hours until the stools have remained normal for two days. The duration of treatment should not exceed 14 days. In many cases a lower dosage might well suffice. More recent work has pointed to the superiority of succinyl sulphathiazole (sulphasuxidine) and of sulphadiazine. The dosage for an adult of succinyl sulphathiazole need not exceed 10 gm. daily, divided into five doses (see Smyth *et al.* 1943, Report 1943*b*, Roberts and Daniels 1943). Sulphadiazine is recommended by Hardy, Burns and DeCapito (1943) for acute cases and succinyl sulphathiazole for convalescents and latent carriers. In very severe cases due to the Shiga bacillus it is well to combine chemotherapy with serum treatment. On the whole the available evidence seems to show that treatment with adequate doses of sulphaguanidine, sulphadiazine, or succinyl sulphathiazole cuts short the acute symptoms of the disease and lessens the chance of the patient's becoming a convalescent or chronic carrier. Once the carrier state is established, the value of sulphonamide treatment appears to be less. It is, however, always worth trying, and is often successful in Flexner and Shiga infections (Rantz and Kirby 1942, de Candole 1943); Sonne carriers appear to be more refractory, though favourable results have been reported with succinyl sulphathiazole (Brewer 1944).

CHAPTER 71

INFECTIVE ENTERITIS OF INFANCY

THE title of this chapter suggests that there is an infective and a non-infective enteritis of infancy, and that the two diseases can be distinguished. The first suggestion is doubtless correct; but though some cases are certainly infective and others are almost certainly not, there is a substantial modicum of cases between these two extremes that cannot be assigned with any assurance to one or other group. Our knowledge of the causative factors underlying much of the enteritis of infancy is very incomplete; and all we can do in this chapter is to discuss certain types of enteritis which, either on bacteriological or on epidemiological grounds, appear to be infective. Since no satisfactory classification can yet be made on an ætiological basis we shall, for convenience of description, divide the cases in a provisional and arbitrary manner into the following groups, realizing that, in opposition to all the canons of classification, the groups themselves are not mutually exclusive.

1. Neonatal diarrhœa.
2. Primary infective enteritis due to known pathogenic organisms.
3. Primary infective enteritis due to, or associated with, organisms of doubtful pathogenicity—summer diarrhœa.
4. Enteritis following the consumption of food containing toxic substances of bacterial origin.
5. Infective enteritis of protozoal origin.
6. Infective enteritis, secondary to or associated with parenteral infection.

Epidemiology.—Though each of the six groups just mentioned has its own peculiar epidemiology, it will be well to give a picture of the disease as a whole. No satisfactory data exist on the incidence of infantile enteritis, either of the infective or of the non-infective type. It is probable, however, that the mortality figures, on which we shall have to rely, comprise mainly the infective cases. In considering the disease we shall not restrict ourselves entirely to infants under one year of age, but shall at times extend our survey to include children up to five years of age.

It will be seen from Table 143 that the death rate from diarrhœal diseases in infants fell considerably during the first 30 years of the present century, so that in the 1931–35 quinquennium it was only about 15 per cent. of what it was at the close of the last century. Since 1930, however, the rate has remained more or less stable.

Table 144 shows that the great majority of fatal cases occur during the first year of life, and that about 95 per cent. of deaths under five years of age occur

TABLE 143

AVERAGE ANNUAL DEATH RATE FROM DIARRHŒAL DISEASES IN INFANTS UNDER 1 YEAR OF AGE PER 1,000 LIVE BIRTHS. ENGLAND AND WALES.

Years.	Average. Annual Death Rate.	Years.	Average. Annual Death Rate.
1896–1900 . . .	31	1921–25	8
1901–05. . . .	23	1926–30	6
1906–10. . . .	18	1931–35	5
1911–15. . . .	19	1936	5
1916–20. . . .	9	1937	5

during the first two years. The footnote shows that the death rate is higher in males than in females.

Table 145 records the deaths from diarrhœa and enteritis according to the month of the year. Though deaths at all ages are included, it will be realized

TABLE 144

DEATHS AT AGES FROM DIARRHŒA AND ENTERITIS. ENGLAND AND WALES.

Year.	Age in Years.						
	0–1.	1–2.	2–3.	3–4.	4–5.	0–5.	All Ages.
1911	31,899	6,901	1,097	380	185	40,462	46,212
1916	2,391	702	144	48	21	3,306	14,041
1921	11,705	1,924	320	154	102	14,205	17,086
1926	5,394	969	201	129	77	6,770	8,415
1931	3,284	447	99	55	48	3,933	5,222
1936	3,220	260	74	37	25	3,616	4,990
1937	3,086	296	61	34	29	3,506	4,925

NOTE.—During these years 55·8 per cent. of the deaths under 5 years of age were in males.

from the previous table that the majority of them refer to deaths during the first two years of life. It is evident that in the hot year of 1921 there was a striking seasonal incidence, the deaths during the months of August, September and October exceeding those during the other nine months of the year. Though detailed figures are not provided in the Registrar-General's report, it is known

TABLE 145

DEATHS FROM DIARRHŒA AND ENTERITIS ACCORDING TO MONTH OF THE YEAR. (ENGLAND AND WALES. ALL AGES)

Year.	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.
1921	942	775	793	614	600	581	1,591	3,880	3,066	2,306	1,162	763
1926	585	457	436	473	461	442	569	896	1,546	1,309	655	579
1931	538	377	472	399	407	380	390	403	433	461	476	476
1936	398	396	463	382	407	339	397	400	481	522	401	393
1937	355	328	386	351	427	373	408	433	470	459	441	490

that in the hot year of 1911, when there was a very high diarrhœal mortality, the majority of the deaths likewise occurred during the same period. Since 1921, in spite of seven hot years, the gross excess of deaths during the late summer and early autumn has not been witnessed again, and there is now little evidence of seasonal variation in the death rate (see Graham-Smith 1939).

Most authors stress the protective influence of breast-feeding. Niven (1904), for example, in Manchester, found that of 88 infants under one year of age suffering from summer diarrhœa, all but four were artificially fed. Dudfield (1912) in Paddington estimated that in 1911 the attack rate of breast-fed infants was 28·3 per cent., and of those artificially fed 58·6 per cent.; in the former group not a single infant died. Peters (1910) brought evidence to show that infants in the first year were more susceptible when artificially fed than those in the second year; we may conclude, therefore, that breast-feeding is responsible for delaying the onset of the disease. Further evidence of the protective effect of breast-feeding was contributed by Grulee, Sanford and Schwartz (1935) in the United States, who analysed the morbidity and mortality statistics relating to 20,000 infants, and found that the incidence of gastro-intestinal disorders was considerably higher in the artificially than in the breast-fed group. Several other authors could be quoted to the same effect. Without wishing in any way to belittle the importance of breast-feeding, we may point out that it is hardly fair to form an estimate of the superiority of breast over artificial feeding by merely comparing the incidence or mortality of diarrhœa in the two groups of children. As Dr. A. Bradford Hill pointed out to us some years ago, there is a fallacy in assuming that the two groups are strictly comparable. The mere fact that an infant is artificially fed often means that it was not thriving at the breast. The artificially fed group therefore must contain a proportion of infants suffering from disturbed digestion of one sort or another, and it is in consequence not surprising that these should be more prone to develop enteritis than infants who are responding perfectly well to breast-feeding. Other factors, too, such as social status and environment, must tend to upset the comparison in favour of the breast-fed group. If alternate children under exactly similar conditions could be reared on the breast and on an artificial diet, it is probable that the mortality from enteritis would be lower in the breast-fed group, but the difference between the two groups would almost certainly be considerably less than that indicated by most of the figures quoted. Breast-feeding is beneficial, partly because human milk is on the whole more easily digested than cows' milk; and partly because breast milk is not subject to contamination from fingers, flies and other sources to which liquid cows' milk is often exposed, and to which the devastating outbreaks of summer diarrhœa that occurred in the early years of the present century can be largely ascribed.

Social and environmental factors play a part in the epidemiology of infantile enteritis. Broadly speaking, the lower the social class, the greater the degree of overcrowding in the homes, and the dirtier the domestic conditions, the commoner is the disease. Poorly nourished babies are more likely to be affected than those which are well nourished. The disease is particularly prevalent in hospitals and institutions, where it constitutes a serious hazard to life. Dobbs (1941), for example, goes so far as to say that gastro-enteritis is the greatest menace to infants suffering from pyloric stenosis admitted to English hospitals. Premature infants nursed in hospitals, particularly if they are not breast-fed, are likewise peculiarly subject to the disease.

Neonatal Diarrhœa

This disease, which is sometimes referred to as epidemic diarrhœa of the newborn, has attracted attention only during recent years. Rice, Best, Frant and Abramson in 1937 were able to collect reports on eight outbreaks, but since then numerous others have been described in the United States and Great Britain. Our information, however, about the disease is still fragmentary, and its ætiology remains obscure. Almost all the reported outbreaks have occurred in maternity homes; but it is quite possible that sporadic cases occur which are not recognized as being of the same nature as the epidemic disease. Infants are said to be attacked chiefly in the first fortnight after birth, but again too much weight should not be laid on this statement, because this happens to be the usual length of stay in a maternity home. Infants developing the disease after they have left the home will often be overlooked. Ormiston (1941), describing one outbreak, mentions that when, for various causes, infants were kept in hospital for longer than the usual 10- to 14-day period, 46 per cent. were older than a fortnight when first affected. On the whole, however, the evidence does suggest that the disease is restricted to infants under one month of age, and that the commonest age at the time of onset is 5 to 8 days. There is no apparent difference in sex incidence; and though infants of the poorer classes are said to be more susceptible than those of the wealthier classes, social distinctions do not appear to be of great importance (Frant and Abramson 1938). Reports on the relative incidence of the disease in breast-fed and artificially fed infants are conflicting (Rice *et al.* 1937, Best 1938, Baker 1939, Forbes and Olsen 1939, Cron *et al.* 1940, Ormiston 1941). Many authors have observed no difference between the two groups; but this may perhaps be partly explained by the common custom in maternity hospitals of giving glucose water or some similar drink to all babies, thus affording a possible means of spreading infection. It is difficult to estimate the true morbidity of this disease.

Rice, Best, Frant and Abramson (1937) say that among 3,672 babies born alive in eleven lying-in institutions in New York City between July, 1934, and December, 1936, 505 are known to have contracted neonatal diarrhœa—a morbidity rate of 14 per cent. Among these the case-mortality rate was 46 per cent. Greenberg and Wronker (1938), referring to a New York hospital, mention a morbidity rate of 40 per cent. and a case-mortality rate of 29 per cent. In Great Britain Ormiston (1941) described outbreaks in three geographically separated institutions, and observed among 996 exposed infants a morbidity rate of 14 per cent. and a case-mortality rate of 29 per cent. In Sakula's (1943) series of 25 cases, no fewer than 20 deaths occurred.

Most authors agree on the high case-mortality rate, which may reach even 80 per cent., but the high morbidity rates just quoted must be understood to refer only to institutions in which the disease occurs. So far as can be ascertained from reported figures, the disease is unknown in the majority of maternity hospitals, so that its total incidence is probably low. There is little to suggest any particular seasonal prevalence; outbreaks occur in the winter as well as the summer. The incubation period may be as short as 2 days or as long as 20 days; the commonest period seems to be 2 to 6 days. In any given nursery there may be two or three sporadic cases, followed by a rapid succession of cases, giving to the outbreak an almost explosive suddenness; or there may be small groups of cases separated by intervals of a week or more.

This is not the place to describe the symptomatology of the disease. Briefly, however, the chief manifestations are a sudden or insidious onset, vomiting, slight

fever, diarrhœa, rapid dehydration and loss of weight, often followed by death in 1 to 7 days. Blood, mucus or pus in the stools are uncommon. At autopsy, the findings vary greatly. Often there is little to be seen besides congestion of the intestinal mucosa and slight swelling of the mesenteric lymph nodes. Sometimes there are hæmorrhagic pneumonia and acute hæmorrhage splenitis (Colvin and Emory 1941); and sometimes cerebral œdema and petechial hæmorrhages in the brain and viscera (Lyon and Folsom 1941, Bloch 1941). Acute enteritis may be found (Cron, Shutter and Lahmann 1940), but usually this is conspicuous by its absence.

Bacteriologically, with the exception of a single outbreak described by McKinlay (1937) in which a salmonella—later identified by Schiff and Strauss (1939) as *Salm. wichita*—was isolated from the stools, the findings of different workers have been unilluminating. The possible causation of the disease is discussed by Crowley, Downie, Fulton and Wilson (1941), who are unable to reach any definite conclusions. Many workers favour a virus infection, supporting this by the apparent relationship of some outbreaks in infants to the occurrence of epidemic influenza in the general population; others regard as a more probable cause some normal inhabitant of the intestine which is virulent for infants but not for older children. The general picture of the disease suggests an acute toxæmia, but what the nature or origin of the toxin is remains obscure. Light and Hodes (1943) claim to have demonstrated the presence of a filtrable agent in the stools, capable of giving rise to acute enteritis in calves; but their work awaits confirmation.

Spread of the disease is difficult to control by ordinary measures. Usually it is best to close the maternity home to further admissions, remove infected infants to suitable isolation quarters, discharge apparently healthy infants, and then disinfect the whole premises as thoroughly as possible.

Primary Infective Diarrhœa due to known Pathogenic Organisms

Observations, particularly during recent years, have rendered it evident that some cases of enteritis during infancy and early childhood are due to infection with members of the *Shigella* or *Salmonella* group. How frequent these are, it is impossible to say. In the past many cases have probably not been recognized, owing to imperfect bacteriological technique; but now that increasing attention is being drawn to these organisms, and highly selective media are available for their cultivation, they should be diagnosed more frequently.

Hormaeche (1943) who, with his colleagues, conducted a very careful investigation into the enteritis of infancy in Uruguay, found that of 668 cases of enteritis, 260 (38·9 per cent.) were due to *Shigella* and 152 (22·8 per cent.) to *Salmonella*; in the remaining 256 cases (38·3 per cent.) no pathogenic organisms could be demonstrated. The incidence of dysentery and salmonella infections is probably much lower in this country than in Uruguay; but that it is not negligible is shown by the fact that Blacklock and Guthrie (1937), working at the Royal Hospital for Sick Children, Glasgow, investigated during the years 1931–36 no fewer than 215 cases of dysentery in children up to 12 years of age, and Guthrie and Montgomery (1939), at Glasgow, investigated, apparently during the years 1937 and 1938, 28 cases of *Salmonella* infection in infants under two years of age. In Syria, Moore and Dennis (1940) studied 543 attacks of enteritis occurring in 490 infants and children, and found that 65 were due to dysentery bacilli, 11 to proved *Salmonella* strains, and 51 to strains that gave the correct sugar reactions of the *Salmonella* group but were not serologically identified.

Both dysentery and salmonella infections are said to be commoner in children than in infants. Whether this is so or not is doubtful. What does seem to be clear is that the case mortality is much higher during the first two years of life than later (Table 146).

TABLE 146

CASE MORTALITY OF ENTERITIS ACCORDING TO CAUSE AND AGE.
(From Hormaeche, 1940)

Age in Years.	Shigella Infections.		Salmonella Infections.		Cause Unknown.	
	Cases.	C.M. %.	Cases.	C.M. %.	Cases.	C.M. %.
0–1	51	45·1	39	30·7	135	28·9
1–2	41	31·7	20	15·0	39	23·1
2–3	18	5·6	11	0·0	9	33·3
3–12	16	0·0	10	0·0	6	0·0

C.M. = Case Mortality.

Pathologically, the disease tends to be more of an ileo-colitis than a gastro-enteritis. This is manifested clinically by the frequent occurrence of dysenteriform symptoms, and by the presence of blood, mucus and pus in the stools. Less often, the upper part of the intestine is attacked; the diarrhœa may then be of the frequent watery type, leading to rapid dehydration—the so-called cholera nostras or cholera infantum. Except in rare instances dysentery bacilli remain confined to the gut, but salmonella bacilli often invade the blood stream, giving rise to septicæmia or meningitis (Hormæche, Peluffo and Aleppo 1940). The commonest types of dysentery bacilli are *Sh. flexneri, Sh. sonnei* and *Sh. newcastle.* Of the *Salmonella* group, numerous members have been encountered, notably the *typhi-murium, newport, enteritidis, dublin* and *derby* types.

Bacteriological diagnosis is made in the usual way. The organisms should be cultivated from the fæces, using desoxycholate citrate agar for the dysentery group, and this medium, together with preliminary enrichment in brilliant green tetrathionate or selenite broth, for the *Salmonella* group. Sometimes *Salmonella* may be isolated from the throat, the middle ear, the cerebrospinal fluid or the blood. Serum agglutinins appear in a considerable proportion of the cases, particularly in older children, and are best demonstrated 2 to 3 weeks after the beginning of the disease (Hormaeche, Surraco and Aleppo 1939, Hormaeche, Peluffo and Aleppo 1940).

Primary Infective Enteritis due to, or associated with, Organisms of Doubtful Pathogenicity

This group contains the great mass of cases of unknown ætiology. In the last century and the early years of this century it was particularly prevalent during the late summer and early autumn months—the so-called summer diarrhœa of infants—and was responsible in hot years for a large number of deaths. Now, the summer excess is no longer seen, but the cases that occur throughout the year remain equally unexplained and puzzling.

Summer Diarrhœa.—Briefly, this disease used to be common both in Europe and in America. In hot summers it attained epidemic proportions. It was most

frequent in the second year of life, but the case mortality was highest 3 to 6 months after birth, when it sometimes reached a figure of 30–40 per cent. Breast-fed infants were comparatively exempt. The children of the poorer classes, living in hot, dirty, overcrowded tenements, suffered most severely. Its infectious nature was suggested by the occurrence of multiple cases in the same household (Niven 1904, Peters 1910, Sandilands 1910, Hutt 1914).

Ballard (1889) drew attention to the importance of temperature in the genesis of the disease. In his own words: "The summer rise of diarrhœal mortality does not commence until the mean temperature recorded by the 4-foot earth thermometer has attained somewhere about 56° F., no matter what may have been the temperature previously attained by the atmosphere or recorded by the 1-foot earth thermometer." He pointed out, too, that the maximal diarrhœal mortality of the year was usually observed in the week in which the 4-foot earth thermometer recorded its maximum, and that the decline of the diarrhœal mortality coincided with that of the 4-foot earth temperature, which lagged well behind the fall in atmospheric temperature. Influenced by Pettenkofer's doctrine, Ballard believed that the rise in earth temperature favoured the multiplication of some micro-organism, which infected the food and thus gained access to the alimentary canal. Later workers regarded the undoubted effect of temperature in a different light. Niven (1910), for example, working at Manchester, found a close correspondence between the prevalence of flies captured week by week and the incidence and mortality of diarrhœa. Hamer (1908) in London and Hope (1920) in Liverpool confirmed Niven's observations, but pointed out that the two curves were not always parallel (see Fig. 285). In 1916, 1917 and 1918 the two curves agreed closely; but in 1919, though flies were as prevalent as in the three previous years, the curve of diarrhœal mortality was very low.

Besides favouring flies and the consequent infection of food, a high temperature may cause a disturbance of the normal secretory mechanism of the infant's intestine. Arnold (1928), for example, brings evidence suggesting that it diminishes the amount of acid secreted by the stomach, and thus interferes with the gastro-duodenal auto-disinfecting mechanism, which is responsible for keeping the upper part of the intestine relatively free from bacteria. In addition, a high temperature promotes the multiplication of bacteria in milk and similar foods. This factor will clearly be operative to a greater extent in poor-class houses, ill provided with the means of keeping foodstuffs clean and cool, than in the houses of the well-to-do.

The bacteriological findings in summer diarrhœa have been most diverse. They were reviewed in some detail in the 2nd edition of this book (pp. 1250–53). Suffice it to say here that members of the dysentery group, *Proteus morgani*, *Proteus vulgaris*, *Ps. pyocyanea*, *Cl. welchii*, and certain other organisms were all incriminated by workers in different countries; but that no one single pathogenic organism was demonstrated by everybody. The only common finding was that non-lactose-fermenting organisms were greatly increased in the fæces; what the majority of these organisms really were remains in doubt. The bacteriological investigation of summer diarrhœa was carried out at a time when our technical methods were far less developed than they are now, and when several members of the *Shigella* and *Salmonella* groups were unknown. It is fairly clear that no one organism could have been responsible for all cases. We are therefore driven to the conclusion that summer diarrhœa, though appearing epidemiologically to be a well-defined disease, was in fact associated with a multiplicity of bacterial agents.

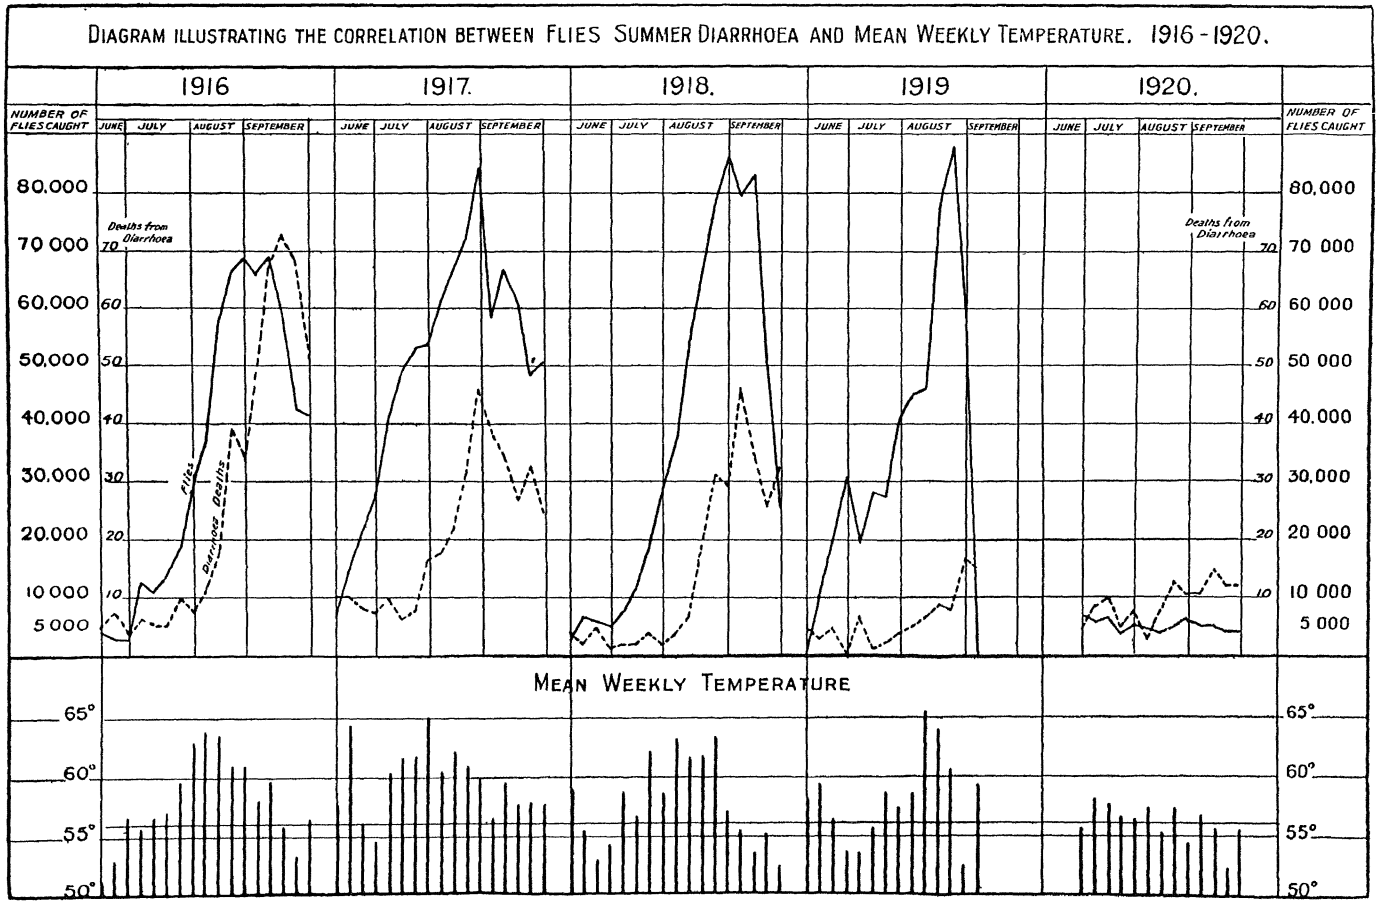

FIG. 285.—AFTER HOPE.

On the whole it seems probable that the disease was a bacterial infection, the prevalence of which was determined by a number of factors, varying to some extent independently, but all conditioned directly or indirectly by the prevailing temperature.

During the past 20 or 30 years, summer diarrhœa has practically disappeared from this country (see Table 145). The better disposal of garbage, the diminution of dust, the replacement of horse by motor traffic, the decrease in the number of flies, the improvement in cleanliness of the milk supply, and the greatly increased use of pasteurized, boiled and dried milk in the feeding of infants and children, have probably all aided in lessening the chances of bacterial contamination of food with pathogenic bacteria.

Enteritis following the Consumption of Food containing Toxic Substances of Bacterial Origin

Little is known of this group. It is included in Lyon's (1940) classification of the diarrhœal diseases of children; but owing to the peculiar difficulty of demonstrating bacterial toxins concerned in food poisoning, other than that formed by *Cl. botulinum*, progress in its study has necessarily been slow. Some strains of staphylococci are known to give rise under favourable conditions to an enterotoxin capable of causing acute gastro-enteritis in adults. The toxin may be formed in milk, and it is therefore almost certain that infants and young children fed on raw cows' milk must be affected from time to time. Whether other common organisms proliferating to a prodigious degree in milk can render the milk toxic to infants, either by virtue of their own body substance or by breaking down some substrate in the milk, is still doubtful. Many years ago Park and Holt (1903) brought evidence to show that milk containing large numbers of coliform bacilli, streptococci and micrococci, i.e. bacteriologically dirty milk, was able to give rise to gastro-intestinal disturbance in infants, but the exact mechanism by which this occurs has so far baffled inquiry (see Chapter 93).

Infective Enteritis of Protozoal Origin

There is considerable reason for believing that the flagellate, *Giardia lamblia*, may give rise to enteritis in infants and young children. This organism hooks itself on to the cells of the duodenal and upper ileal mucosa and, if present in sufficiently large numbers, seems to give rise to inflammation of the gut and possibly to interference with fat absorption (Véghelyi 1938, 1940). Moore and Dennis (1940) in Syria, whose observations have already been referred to, found it in 84 out of 543 attacks of enteritis. In infants, when blood was present in the diarrhœal stools, it was found in 22 per cent. of cases examined, as against only 10 per cent. in all cases of infantile diarrhœa. The difficulty in determining its pathogenicity lies in the circumstance that it is often found in the complete absence of symptoms, and that its increased frequency in the stools in the presence of diarrhœa may be explained by the more rapid passage of the organisms through the gut in an unaltered condition. The clinical evidence, however, in favour of its pathogenicity is fairly strong, and the disappearance of symptoms after treatment with mepacrine lends added weight to this view (see Ormiston, Taylor and Wilson 1942). The type of enteritis to which it appears to give rise may be acute, and be characterized by vomiting and diarrhœa, sometimes with mucus and traces of blood in the stools; but more often it is mild and chronic and is

characterized by 3 or 4 copious, loose, evil-smelling motions a day. The disease is seldom fatal.

Mepacrine has the same specific action on *Giardia* as it has on the malarial parasite. One-sixth of a 0·1 gm. tablet given three times a day for 5 days to a child of 1 to 2 years of age usually effects a complete cure. After treatment, most children seem to remain immune for a long time, but a proportion of them become re-infected after a year or so, and may again suffer from enteritis.

Infective Enteritis, secondary to or associated with Parenteral Infection

The observation that infants and young children suffering from inflammation of the respiratory, or less often of the urinary, tract may develop diarrhœa and vomiting, has led many clinical workers to believe that practically all infective gastro-enteritis is secondary to parenteral infection. We do not propose to discuss this thesis in detail (see Smellie 1939). Careful bacteriological and pathological studies have failed to support it, and in its extreme form it is clearly untenable. Nevertheless, parenteral infection is very often present in acute gastro-enteritis, and it should invariably be sought for and excluded.

Smellie (1939) in Birmingham found that of 500 patients suffering from enteritis on admission to hospital, 231 showed unequivocal signs of parenteral infection—mainly otitis, mastoiditis or bronchitis—that 90 others developed clinical signs of parenteral infection after admission, and that 28 further children who died and came to autopsy were found to have an infection that had not been detected clinically. Bonaba and Peluffo (1940) in Uruguay recognized the presence of parenteral infection—mainly rhino-pharyngitis and otitis—in 379 out of their series of 768 patients. Campbell and Cunningham (1941), at the Park Hospital, London, studying 574 cases of non-specific gastro-enteritis, observed that 175 of them had parenteral infection on admission—mainly tonsillitis, laryngitis, bronchitis, or bronchopneumonia—and that 58 others developed it after admission. The first set had a case mortality of 23·4 per cent., the second set of 32·5 per cent. The average case mortality for the whole series of 574 cases was 27·7 per cent., so that the occurrence of parenteral infection did not appear to have much effect on the fatality of the disease.

In estimating the causal relationship of parenteral infection to gastro-enteritis it is well to remember that large numbers of children who suffer from respiratory infection do not develop gastro-enteritis, and that often quite a high proportion of cases of true dysentery develop parenteral infection (Marriott *et al.* 1933). Respiratory infections are much commoner in the winter than the summer, whereas gastro-enteritis tends, if anything, to show the reverse seasonal incidence. It is improbable, therefore, that parenteral infection is responsible for more than a proportion of cases of gastro-enteritis.

Prophylaxis and Treatment

Broadly speaking, the prevention of enteritis lies in the protection of the food supply from contamination, the provision of good general hygienic conditions, and the separation as far as possible from each other of infants and children under 2 years of age. Reference has already been made under summer diarrhœa to the beneficial effect of reducing the fly population, and to the replacement of raw by pasteurized, boiled or dried milk. Whenever possible, breast-feeding should be preferred to artificial feeding. Raw cows' milk may be contaminated from so many different sources—the cow itself, the personnel handling the milk, impure

water used for cleansing the utensils, dirty bottles, flies, and rodents—that it should never be given to infants and young children. Even milk produced under cleanly conditions on the farm, such as Tuberculin Tested milk, may be contaminated from one or more of the sources just mentioned, and should therefore always be pasteurized or brought rapidly to the boil and cooled. The importance of good hygienic conditions is obvious. In particular, care should be exercised to protect infants against exposure to undue heat or cold, and to minimize their risk of contact with other persons suffering from respiratory or intestinal infection. The desirability of rearing infants during their first two years of life under relatively segregated conditions is not yet fully appreciated. Infantile diarrhœa is so common in institutions that no encouragement should be given to the establishment of nurseries for children under 2 years of age. No infant should be admitted to a hospital for treatment of any form if this can be carried out effectively at home (see Field, MacCarthy, and Wyllie 1943). Numbers of infants die unnecessarily every year as the result of contracting gastro-enteritis in hospitals to which they have been admitted, sometimes for relatively trivial causes. Doctors and nurses should be taught to realize that the decision to admit an infant to hospital is one that should never be taken lightly; the consequences may easily be fatal. There are diseases, however, which cannot adequately be treated in the home. Infants' wards should therefore be divided into cubicles, and each occupant treated with strict precautions to avoid cross-infection. Even the maternity home should be run ideally on the cubicle system. When this is not possible, infants should be warded with their mothers and not taken away to sleep in a common nursery where, if infection is introduced, it is liable to spread rapidly.

Once gastro-enteritis has broken out in a hospital or maternity home, the measures to control it must depend to some extent on its nature and severity. Neonatal diarrhœa demands instant and rigorous action. The maternity home should be closed at once to further admissions, affected infants must be removed to suitable isolation quarters, apparently healthy infants should be sent home and kept under supervision, and the whole premises must be thoroughly cleaned and disinfected. Dysentery in a children's ward is often difficult to eradicate, but the prompt removal of all recognized cases, the detection and segregation of carriers among both the patients and the nurses, and the proper disinfection of napkins and bed linen will often prove successful.

The treatment of the individual patient falls largely outside our scope. It is interesting, however, to note that sulphonamide treatment may be of value, not only in dysenteric infections (see Chapter 70), but even in neonatal diarrhœa. Henderson (1943) has reported a striking effect of sulphaguanidine on the case mortality of this disease in the Simpson Maternity Hospital, Edinburgh. He recommends that the drug should be given in a dosage of 0·5 gm. every 4 hours for several days, and that it should not be reduced until there is clinical improvement and return of appetite. On the other hand, in ordinary infantile gastro-enteritis McSweeney (1943) observed no benefit from treatment with sulphaguanidine. Promising results have been reported by Twyman and Horton (1943) from the use of succinyl sulphathiazole.

CHAPTER 72

BACTERIAL FOOD POISONING AND BOTULISM

FOOD POISONING

Definition.—The consumption of unwholesome food or drink may give rise not only to well-known bacterial infections such as enteric fever, dysentery, cholera, tuberculosis, undulant fever, scarlet fever, septic sore throat, and so on, and to helminth infections such as trichinosis, in which the food serves as a vehicle for the specific infective organism, but also to such diverse conditions as those due to the ingestion of inherently poisonous substances—for example deadly nightshade, hemlock, poisonous fish, toadstools, and ergot-infected grain—and those in which the food has become contaminated directly with such poisons as arsenic, tin, antimony, cadmium or other heavy metals, or with chemicals such as sodium fluoride, or tri-ortho cresyl phosphate, which was responsible for outbreaks of so-called "jake" or "ginger" paralysis in the United States (see Smith and Elvove 1931) and for a similar outbreak in Durban (Sampson 1942). The term "food poisoning," however, is conventionally restricted to acute gastro-enteritis due to the bacterial infection of food or drink. So defined, it is divided into two groups: (1) that following the multiplication within the body of pathogenic organisms contained in the food; this may be referred to as the "infection" type, (2) that following the ingestion of food in which poisonous substances have been formed as the result of bacterial proliferation; this may be referred to as the "toxin" type.

Botulism, which is also a consequence of bacterial proliferation in food, differs from either of the types just described in the character of the symptoms and in the nature of the toxin involved; though, for convenience, it will be discussed in this chapter in a separate section (p. 1612). Those interested in chemical food poisoning may be referred to the works of Jordan (1931), Tanner (1933) and Dack (1943).

It will be noted that the definition given above excludes food idiosyncrasy and food allergy—conditions in which the food itself is wholesome but the patient's reaction is abnormal. In addition, it excludes acute gastro-enteritis, such as is characteristic of the winter vomiting disease (see p. 1798), in which the infection does not seem to be food-borne; and gastro-enteritis associated with malnutrition and starvation (see García and Covián 1942).

Symptomatology.

In the *infection* type of food poisoning, after an incubation period varying from 2 to 36 hours, but generally between 8 and 24 hours, the illness commences with severe headache, followed by nausea, vomiting, diarrhœa and abdominal pain. Fever is usually present; the temperature may rise to 102° F. In favourable cases

the symptoms gradually abate so that the patient is better within a week, but in very severe cases restlessness occurs, followed by extreme thirst, cramp, coma, and death. At autopsy the mucosa of the stomach and intestines is swollen and often intensely congested. Peyer's patches are not particularly affected. Minute ulcers may be seen. Microscopic examination reveals fatty degeneration of the liver. The causative bacilli can be isolated from the heart's blood, spleen, and other viscera in a considerable proportion of fatal cases.

In the *toxin* type of food poisoning, the incubation period as a rule is much shorter—1 to 6 hours, usually 3 hours—though in some outbreaks, probably of non-staphylococcal type, it may be as long as 12 hours. The general symptoms resemble those of the infection type, but vomiting tends to be more violent, diarrhœa is less conspicuous, prostration is greater, fever may be absent, and recovery is more rapid, the patient often being well again within 24 hours. These cases are rarely fatal, so that adequate information about the pathological changes is lacking.

Epidemiology.

Incidence.—It is difficult, in the absence of compulsory notification, to estimate the frequency of food poisoning in this country. From January, 1921, to October, 1923, Savage and White (1925*b*) collected details of 86 outbreaks in Great Britain, involving about 2,300 persons with 24 deaths. But it is probable that a number of other outbreaks occurred which were not sufficiently important to attract attention. In America, Jordan calculated in 1917 that about 15,000 to 20,000 persons a year were attacked. The country that suffers most severely is Germany, probably on account of the large amount of uncooked meat that is consumed. The following figures (Table 147) refer only to outbreaks that were due to meat or meat products. The number of outbreaks from all causes was probably much higher.

TABLE 147

INCIDENCE OF FOOD POISONING IN GERMANY FOLLOWING THE CONSUMPTION OF MEAT AND MEAT PRODUCTS.

(Meyer 1929)

Year.	No. of Outbreaks.	Cases.	Deaths.
1923	76	3,746	28
1924	62	1,712	21
1925	83	1,905	22
1926	84	2,679	17
1927	110	3,548	27
1928	78	977	18

A special survey by the United States Public Health Service revealed, in 1938, 51 outbreaks of food poisoning and gastro-enteritis caused by milk or food affecting 2,459 persons (Frank 1940), and, in 1939, 142 outbreaks affecting 3,976 persons (Fuchs 1941). Reasons were advanced for believing that the total incidence was probably five, ten, or more times as great as that indicated by the collected figures. In England and Wales, the average annual number of outbreaks brought to the notice of the Ministry of Health (Scott 1939) during the years 1929–38 was 69 (see Table 148), but during the second world war, partly because of the increase in communal feeding and partly because of better reporting and investigation, this figure rose very considerably.

TABLE 148

RECORDS OF FOOD POISONING OUTBREAKS IN ENGLAND AND WALES, 1929–38.
(Modified from Scott, 1939)

Year	Total No. of Outbreaks.	*Salmonella* Outbreaks.			Dysentery Outbreaks.	Toxin Outbreaks.	Outbreaks of Doubtful Origin.
		No. of Outbreaks.	Cases.	Deaths.			
1929. .	36	9	68	4	4	5	18
1930. .	25	11	292	16	8	5	1
1931. .	36	18	425	10	2	6	10
1932. .	36*	24	186	8	10	6	?
1933. .	66	32	512	15	4	21	9
1934. .	79	43	125	6	6	24	6
1935. .	113	46	698	23	12	47	6
1936. .	69	19	224	3	8	26	16
1937. .	88	45	601	24	5	22	16
1938. .	138	72	330	8	8	21	37
Total .	686	319	3,461	117	67	183	119

* This number appears to be too low. It may also be noted that the total number of outbreaks given in this table is 69 less than the aggregate recorded in the annual reports of the Chief Medical Officer of the Ministry of Health.

Solitary cases of food poisoning, in which one member only of a family consuming similar food is attacked, are apt to escape diagnosis, the symptoms being ascribed to indigestion, chill, or some other cause, unless a bacteriological examination is made. Such cases are being detected with increasing frequency.

Season.—In this country food poisoning is commoner during the summer than the winter. Savage and White (1925*b*) found that about 72 per cent. of outbreaks occur between May and October. This is probably due to the greater rapidity with which bacteria are able to multiply under warm conditions. But the seasonal incidence depends to a certain extent on the proportion of canned to fresh food that is eaten. In America, for example, it appears to be customary for the housewife to can her vegetable produce in the summer months and to consume it during the winter; since the process of home canning is not altogether satisfactory, outbreaks of poisoning due to the consumption of this food are fairly common in the winter months. Many of these outbreaks, however, are of the botulism type.

Morbidity and Mortality.—One of the striking facts is the high morbidity rate of most outbreaks. Often all who eat the affected food are attacked. Geiger (1923) estimates it at 75–100 per cent. An exception may be made in the case of milk; Savage and White (1925*b*) state that in salmonella infections conveyed by milk the morbidity rate is only 40–50 per cent. Another striking characteristic is the low mortality rate; this is estimated by Geiger (1923) in America as less than 0·5 per cent., by Savage (1920) in England as 1·5 per cent., and by Lentz (1924) in Germany as 4·5 per cent. This last figure probably included cases of botulism, and is therefore too high. Mayer (1913) in Germany, dealing purely with salmonella outbreaks, recorded a mortality rate of only 1 per cent. Taking milk outbreaks alone, Savage and White (1925*b*) find the mortality rate to be less

than 0·2 per cent. Sex has apparently little influence. As regards age, the disease seems to be more fatal in the very young, and in the old.

General Bacteriology of Food Poisoning

Before discussing in detail the various factors concerned in the production of bacterial food poisoning, it may be well to take a brief view of the subject as a whole. Towards the end of last century, largely owing to the work of Brieger (1889), food poisoning came to be regarded as due to the presence in the food of toxic amines or *ptomaines* that had been formed as the result of protein decomposition. The work of Vaillard (1902), Fornario (1906), Cathcart (1906*b*), Savage (1921), and others, however, showed that these bodies were relatively non-toxic to laboratory animals, except when given in doses larger than were ever likely to be ingested under natural conditions. The fact, moreover, that the ptomaines did not appear till protein decomposition had reached an advanced stage, when the food would be repugnant to the normal senses, taken in conjunction with the observation that food poisoning usually results from food which is quite sound in appearance, rendered it doubtful whether these bodies played any part in the causation of the type of illness we are considering.

Belief in ptomaine poisoning received its death-blow, so far as scientific bacteriology was concerned, when it was found that in many outbreaks the food contained organisms of the *Salmonella*, or occasionally the *Shigella*, group. As the result of the work of Savage in this country, and of Jordan in the United States, food poisoning came to be regarded almost as synonymous with food-borne salmonella infection. Further work, however, failed to reveal the presence of these organisms in a considerable proportion of the outbreaks in which an adequate investigation was carried out, particularly in outbreaks following the consumption of canned food. To meet this difficulty Savage (1920, 1923, 1932) (see also Savage and White 1925*a*, *b*) put forward the attractive hypothesis that these outbreaks were due to the ingestion by the patient not of the living salmonella organisms, but of their toxins. It was supposed that the organisms had multiplied in the food prior to its consumption, and had formed thermostable toxic substances. The subsequent cooking to which the food was exposed destroyed the organisms themselves, but did not seriously affect their toxic products, which were therefore able to give rise to food poisoning on ingestion. No adequate confirmatory evidence of the formation of specific exotoxins by members of the *Salmonella* group was forthcoming, and the balance of evidence appeared to be against this view (but see p. 1607).

While bacteriologists were speculating about the causation of the non-salmonella food-poisoning outbreaks, Dack, Jordan, and their colleagues in Chicago (see p. 1605) drew attention to certain outbreaks of poisoning which were proved to be due to the presence in the food of a toxin formed by staphylococci. By observations made on human volunteers, it was shown that certain strains of staphylococci were able to form toxic substances endowed with some degree of thermostability. These findings were of special interest in that they afforded conclusive proof of the formation of bacterial toxins in the food prior to its consumption. Hitherto the only known instance of this was that of botulism—a condition to be described later, in which the anaerobic bacillus, *Cl. botulinum*, gives rise to an extremely potent specific exotoxin with an action, not on the gastro-intestinal mucosa, but on the central nervous system.

Other observations by Jordan and by various continental workers cast serious suspicion on food in which there had been inordinate bacterial multiplication of any type. The inference to be drawn from these observations was that many organisms, non-pathogenic in themselves, such as *Bact. coli*, *Proteus vulgaris*, *Proteus morgani*, milk streptococci and others, when allowed to multiply under favourable conditions in suitable types of food-stuffs, led to the appearance of toxic substances having an irritating effect on the human gastro-intestinal mucosa. Many workers had toyed with this idea of non-specific toxin formation, but had abandoned it in the absence of adequate evidence. The epidemiological, and more recently the bacteriological, evidence seems to us, however, to be becoming increasingly strong in favour of this view. The pendulum is in fact slowly swinging in the direction of the old " ptomaine " theory, with the distinction that the poisons now regarded as responsible are not the result of advanced protein decomposition, but result from the growth of types of bacteria which can proliferate enormously without greatly altering the appearance and taste of the food. What the nature of these products is remains in doubt. The suggestion that they consist of the autolysed bacterial bodies themselves (see Jordan 1931, Jordan and Burrows 1935, Savage 1933, Report 1934) is not borne out by human volunteer experiments, and it seems more probable that they consist of some breakdown product formed from the food, or of a bacterial enzyme which has a specific affinity for some constituent of the human gastro-intestinal tract.

Summing up, we may say that bacterial food poisoning may be due (1) to infection with living *Salmonella*, or occasionally dysentery, bacilli, (2) to intoxication with substances, whose nature and mode of origin is as yet imperfectly understood, which are formed as the result of undue bacterial multiplication in the food.

Bacteriology and Epidemiology of the " Infection " type of Food Poisoning

In 1888 Gaertner isolated an organism known as *Salm. enteritidis*, from the meat of an emergency-slaughtered cow, at Frankenhausen in Germany. The meat had been consumed by 58 persons, all of whom developed food poisoning. One man who had eaten about 1½ lb. died in 36 hours. At autopsy, the same bacillus was isolated from the organs of the cadaver as from the meat. In 1898, Durham in England and de Nobele in Belgium described another organism, which they had isolated simultaneously from patients suffering from meat poisoning and from the meat that they had consumed. This organism was known until recently as *Salm. œrtrycke*—Ærtrycke being the name of the Belgian village where the outbreak occurred. It is now, however, called *Salm. typhi-murium*, this being the name given to an organism which was isolated by Loeffler in 1892 from a mouse epizoötic, and which was subsequently found to be identical with *Salm. œrtrycke*.

The intensive study of the *Salmonella* group during the past few years has brought to light a number of other organisms concerned in the production of food poisoning. The frequency distribution of these types varies in different countries. Table 149 shows the distribution in Great Britain, as revealed by examinations carried out from 1923 by the late Dr. W. M. Scott at the Ministry of Health laboratory, and from 1941 onwards by the Emergency Public Health Laboratory Service.

It will be noted that up till 1942 all but a few strains belonged to 14 types, the most important of which were *Salm. typhi-murium*, *Salm. enteritidis*, *Salm. thompson*, *Salm. newport* and *Salm. choleræ-suis*. Of the remaining types listed

TABLE 149

NOTE.—The figures refer to the number of outbreaks, *not* to the number of strains studied.

above the line, all but *Salm. bovis-morbificans, Salm. potsdam* and *Salm. senftenberg* had been first isolated in Great Britain itself. In 1942, however, a remarkable change became apparent. In addition to the old well-recognized types, 10 new types were isolated, the commonest of which was *Salm. oranienburg*. In 1943,

another 8 new types were identified. With the exception of *Salm. chester* and *Salm. cardiff*, every one of these new types had been first described abroad, many of them in the United States. From epidemiological investigations made at the time there is little doubt that the majority of the new types were introduced into Great Britain by American spray-dried egg, which was first distributed on a large scale in the middle of 1942 (see p. 1599).

In the United States, Edwards and Bruner (1943) published records of 194 salmonella strains isolated from the fæces of patients suffering from gastro-enteritis. Of these, the commonest were as follows : *Salm. typhi-murium* 45, *Salm. newport* 31, *Salm. panama* 14, *Salm. oranienburg* 13, *Salm. san-diego* 11, *Salm. bareilly* 9, *Salm. montevideo* 9, *Salm. enteritidis* 8, *Salm. give* 7, *Salm. anatum* 7, *Salm. choleræ-suis* 6, *Salm. newington* 5, *Salm. bredeney* 5 and *Salm. thompson* 4. Many of these, it will be observed, were the same as the types met with from 1942 onwards in Great Britain. The comparative infrequency in the American list of *Salm. enteritidis* and *Salm. thompson*, which were the second and third commonest organisms in Great Britain before the war, is very striking. Further records of the distribution of salmonella strains in the United States will be found in papers by Seligmann, Saphra and Wassermann (1943) and Rubenstein, Feemster and Smith (1944).

In Denmark, during the years 1936–40, the types most often responsible for outbreaks of food poisoning were *Salm. typhi-murium*, *Salm. enteritidis* and *Salm. dublin* (Harhoff 1941). In all three countries, therefore, *Salm. typhi-murium* heads the list.

Besides members of the *Salmonella* group, certain organisms of the dysentery group, particularly *Sh. sonnei* and *Sh. flexneri*, may be concerned in the production of food poisoning. More usually these organisms give rise to dysentery, but occasionally their ingestion in food is followed by typical gastro-enteritis (Clayton and Hunter 1928, Sowden 1933, Scott 1936).

The proportion of total food-poisoning outbreaks constituted by salmonella infections is difficult to assess accurately. In 112 outbreaks in the British Isles recorded by Savage (1920), 39 were shown to be due to bacilli of this group. In 100 later outbreaks recorded by Savage and White (1925*b*), these bacilli were isolated in only 20 instances. Scott's experience at the Ministry of Health (see Table 148) suggests that about 40 per cent. of the severer outbreaks are due to salmonella infections.

Animal Reservoirs of Salmonella.—Though human infection with *Salmonella* is widespread and frequent, the majority of food-poisoning outbreaks due to this group of organisms follow the consumption of food directly or indirectly associated with infection of some animal. We may therefore consider briefly the distribution of *Salmonella* in the common domestic animals and birds.

Ducks.—Salmonella infection of these birds, mainly with the *typhi-murium*, *anatum*, *enteritidis* var. *essen*, *dublin* and *newington* types, appears to be not uncommon.

Beller and Reinhard (1934) in Germany, who examined 1,500 ducks' eggs from 34 farms, found that about 1 per cent. of them contained salmonella organisms. Infection was present on seven of the farms, and about 2–8 per cent. of the eggs from these farms were infected. Lerche (1936*b*) isolated *Salm. typhi-murium* from 19 out of 332 ducks' eggs bought in Berlin. Edwards (1939) refers to 5 outbreaks in the United States due to *Salmonella*. In this country Gordon (1940) examined 21,000 samples of blood from adult ducks, and found agglutinins to *Salm. typhi-murium* or *Salm. enteritidis* in 4·6 per cent. of them.

Salmonella infection of **fowls,** i.e. chickens and hens, appears to be more widespread than in ducks, though according to Gordon (1940) the resulting disease is less often fatal in chicks than in ducklings.

Infection of fowls in Germany with *Salm. typhi-murium* has been described by Beller and Zeki (1934), and with *Salm. dublin* by Lütje (1937). In the United States Edwards and Bruner (1943) have records of 862 outbreaks in fowls, omitting those due to *Salm. pullorum*, *Salm. gallinarum* and *Salm. paratyphi B*. It seems clear, however, that these authors use the word " fowl " in an extended sense, and probably include in it not only chickens and hens, but ducks, pigeons, turkeys and canaries. Mallmann, Ryff and Matthews (1942) have collected records of 17 different types of *Salmonella* infecting fowls, omitting the *pullorum*, *gallinarum*, *paratyphi A* and *paratyphi B* types. In addition, they found 3 new types themselves. Taking their records with those published by Edwards (1939), we give the following list of 24 species of *Salmonella* found in chickens and hens in the United States: *typhi-murium*, *anatum*, *enteritidis*, *oranienburg*, *bareilly*, *dublin*, *montevideo*, *kentucky*, *minnesota*, *worthington*, *derby*, *newport*, *choleræ-suis*, *amersfoort*, *muenchen*, *newington*, *senftenberg*, *new-brunswick*, *london*, *give*, *aberdeen*, *california*, *urbana* and *hvittingfoss*. In this country salmonella strains have been isolated from about 10 per cent. of over 6,000 samples of spray-dried egg powder, most of which came from the United States. The commonest types were *oranienburg*, *montevideo*, *meleagridis*, *bareilly* and *anatum*, but several others were met with. Twelve types, not mentioned in the list given above, were isolated, namely *bovis-morbificans*, *bredeney*, *cerro*, *habana*, *manhattan*, *oregon*, *potsdam*, *stanley*, *sundsvall*, *tennessee*, *california*, and *litchfield*. In Great Britain salmonella infection of fowls is not uncommon; apart from *Salm. pullorum* and *Salm. gallinarum*, the chief type isolated so far has been *Salm. thompson*.

From these results it may be concluded that, at least in the United States, infection of fowls with potential food-poisoning types is widespread, and that eggs or egg products are often infected with *Salmonella*. It is well known, of course, that fowls often suffer from bacillary white diarrhœa due to *Salm. pullorum*, and ducks from keel disease due to *Salm. anatum* ; but, though both these organisms may occasionally infect man, neither is of the same public health importance as the more common food-poisoning types.

The eggs may be infected during their formation in the oviduct, or by passage of the organisms through the shell from the fæces on the exterior (Scott 1933, Kathe and Lerche 1936, Lerche 1936*b*, Jansen 1937). Salmonella organisms may survive for at least 5 months at room temperature in infected fæces (Lerche 1936*a*). Their passage through the shell depends on a number of factors. Provided it is dry, little penetration is likely to occur, and the bactericidal effect of the egg albumen will probably prevent multiplication of the few organisms that may gain access to the interior. If, however, a warm, newly laid egg is brought into contact with fluid containing bacteria at a lower temperature than the egg itself, bacteria are readily sucked through the shell as the egg cools (Haines and Moran 1940). Whether multiplication occurs in the yolk is doubtful; but it is well to remember that, according to Prescott and Tanner (1938), most foods must be stored at 5° C. or less to ensure that no growth of these organisms takes place.

Pigs rival fowls in the frequency with which they are infected with *Salmonella*.

In Uruguay, Hormaeche and Salsamendi (1936) examined the pooled mesenteric lymph nodes from 20 normal animals at a time. Salmonella organisms were isolated from 22 out of 52 batches. An even higher proportion of positive results was obtained by the same authors (1939) in a later investigation. In this country, Scott (1940) examined pooled mesenteric lymph nodes and pooled spleens from apparently normal pigs, and

isolated *Salmonella* from 36 out of 100 batches, representing an aggregate of 1,000 pigs. The lymph nodes were far more often infected than the spleen. In the United States, Rubin, Scherago and Weaver (1942) found that about 10 per cent. of hogs in Lexington contained *Salmonella* in their mesenteric lymph nodes; and Cherry, Scherago and Weaver (1943) isolated *Salmonella* from 5·9 per cent. of retail pig products, mainly brain, chops and liver. In Mexico, Varela and Zozaya (1942) isolated 15 strains of *Salmonella* from mesenteric lymph nodes taken from a total of 209 apparently healthy pigs. The types found in these different countries comprised *choleræ-suis, typhi-murium, thompson, anatum, newport, derby, senftenberg, enteritidis, london, dublin, reading, montevideo, bredeney, newington, muenchen, chester, heidelberg, meleagridis* and *give*. In addition, Edwards and Bruner (1943) include occasional strains of *san-diego, california, bareilly, oregon, manhattan, panama, pullorum, lexington, new-brunswick, illinois, worthington, wichita* and *urbana*. *Salm. choleræ-suis* is probably the commonest type, because of the frequency with which it is found as a secondary invader in swine fever.

Cattle constitute a less important reservoir for *Salmonella* than either fowls or pigs; and the number of different types that have been isolated from them is considerably less.

The observations of Knoth (1936), Bartel (1938), Pohl (1938), and Lütje (1939) in Germany have shown that the two commonest types are *Salm. dublin* and *Salm. typhi-murium*, but that other types, met with much less frequently, include *choleræ-suis, enteritidis, rostock, abortus-equi, abortus-ovis* and *bovis-morbificans*. *Salm. dublin* is pathogenic particularly for calves, in which it gives rise to enteritis or so-called calf dysentery, with or without bronchopneumonia; the joints may be affected, and occasionally a general septicæmia occurs without localizing symptoms. *Salm. typhi-murium*, on the other hand, is found more often in adult cattle, usually in association with severe enteritis. In fatal infections both organisms can often be demonstrated in the spleen, liver, gall-bladder, and hepatic lymph nodes, as well as in the intestine. Metritis, mastitis, and nephritis are sometimes seen.

Apart from *Salm. abortus-ovis*, which may cause abortion, **sheep** are seldom infected with *Salmonella*. The *dublin, typhi-murium* and *enteritidis* types have been isolated occasionally (Bartel 1938), but infection with any of these organisms appears to be rare.

From **horses** the *dublin, typhi-murium, enteritidis* and *bovis-morbificans* types have been isolated (Bartel 1938), as well as the more frequent *Salm. abortus-equi*. The incidence of salmonella infection in these animals is still imperfectly known.

Rodents.—Both rats and mice suffer naturally from infection with *Salm. typhi-murium* and *Salm. enteritidis*.

Savage and White (1923) examined 96 rats from two slaughter-houses. From 6 of them—all from one slaughter-house—*Salm. enteritidis* was isolated; 3 of them were harbouring the organism in their intestines and had presumably been excreting it before death. Moreover, 20 out of 66 rats examined contained agglutinins in their blood serum for *Salm. enteritidis*, varying in titre from 1/40 to 1/800 or higher, probably indicative of either an old or a recent infection. They quote the findings of Savage and Read, who isolated this organism from 5 out of 41 rats examined in 1913. More recently Khalil (1938) examined 750 wild rats trapped in Liverpool. About 70 per cent. were of the large brown and 30 per cent. of the small black variety. Cultures were put up from the liver, spleen and gut. *Salmonella* was isolated from 55 rats, i.e. 7·3 per cent. Of a total of 89 strains isolated, 45 belonged to the *enteritidis*, 40 to the *typhi-murium*, 3 to the *newport*, and 1 to the *thompson* type. In the United States, Welch, Ostrolenk and Bartram (1941) report the isolation of *Salmonella* from 5 out of 420 samples of rat and mouse fæces received from different parts of the country, i.e. 1·2 per cent. The studies

of Topley and his colleagues in this country and of Webster and his colleagues in the United States (see Chapter 56) have shown that infection of rodents with *Salmonella* may result in an acute rapidly fatal septicæmia, a subacute enteritis which may or may not prove fatal, a chronic disease accompanied by changes in the liver and spleen, or by a completely symptomless infection.

Type of Food.—In salmonella outbreaks the incriminated food has generally been meat, milk, fish, or other animal protein such as eggs; vegetables and cereals are less commonly, and fruits rarely, implicated. Moreover the meat has often been made up into pâtés, pies, brawn, jellies, sausages, or other similar products—a process that involves imperfect cooking and liability to contamination. Fresh meat that has been responsible for poisoning will on investigation generally be found to have been stuffed, or re-cooked, or otherwise treated; or it may prove to be ham that has been imperfectly pickled or cooked.

In some outbreaks the food has been prepared and allowed to stand for a time before being eaten; in others it has been heated up again on the 2nd or 3rd days; in others, especially in hot weather, it has been placed in the oven for an hour or so "to prevent its going bad," and not cooked and eaten till the following day.

It is important to remember that the food may, and generally does, appear quite normal to ordinary inspection. To illustrate this, van Ermengem (1896) tells a graphic story of a meat inspector in Belgium who was asked to give his opinion on some suspected sausages. Judging from their excellent appearance, their good smell, and their rosy colour, he pronounced them suitable for consumption, and to demonstrate their harmlessness he ate three slices himself. He developed acute gastro-enteritis, and died in 5 days. From his viscera at autopsy, and from the sausages, *Salm. enteritidis* was isolated. This story illustrates another point of importance—namely, that the distribution of bacilli in an article of food may be quite uneven. Though a large number of sausages were made from the same meat on the same day, only four of them were infected. This is a frequent observation, particularly in relation to canned foods; only one or two cans of a large batch may prove harmful, showing that either the original contamination was localized, or that in the process of sterilization one or two cans, through bad packing or some other cause, failed to be raised to the temperature required to kill the bacilli.

In 68·8 per cent. of the 112 British outbreaks recorded by Savage (1920), in which animal food was the vehicle, the meat was derived from the pig or the ox. Experience in other countries has been much the same. Meyer (1929), for example, reports that, in Germany between the years 1923 and 1928, out of a total of 281 outbreaks in which the animal source of origin was determined, 168 were due to cattle, 60 to pig, and 49 to horse flesh. In 137 other outbreaks sausage meat was the cause, and in a further 75 outbreaks meat of various types had been used.

Of recent years considerable attention has been directed towards poisoning by *eggs*. These have been derived most frequently from ducks, less often from hens and pigeons (Clarenburg and Dornickx 1932, Lovell 1932, Scott 1933, Seligmann 1935, Hohn and Herrmann 1935, Jansen 1936).

The frequency of food poisoning from this source is peculiarly difficult to ascertain, because unless the infected egg is used for preparing a custard, cream filling, or some similar dish, infection is restricted to individuals, and so does not usually come to the notice of the public health authorities. Moreover, the causal relationship is often never even suspected. During the second world war

several new types of *Salmonella* were isolated from cases of food poisoning (see Table 149, p. 1597). Circumstantial evidence suggested very strongly that most of these were derived from the consumption of imported spray-dried egg. This product was not distributed on a large scale till the middle of 1942. Bacteriological examination revealed the presence of *Salmonella* in over 10 per cent. of the samples, the most common types being the same as those most frequently isolated from cases of food poisoning, namely *oranienburg*, *montevideo*, *meleagridis*, *bareilly* and *anatum*. The close parallelism, both chronologically and qualitatively, left little doubt that the egg powder was mainly responsible. The reason why food poisoning due to this cause was not commoner than it was must be ascribed mainly to the consumption of the egg powder soon after reconstitution, so that growth had no time to occur, and to the destructive effect of cooking.

Mode of Infection of the Food.—Briefly, the meat may come from an animal infected during life with a specific organism, or it may come from a healthy animal and be contaminated during the course of preparation for eating.

Enough has already been said to show that salmonella infection of domestic animals is by no means infrequent, particularly among fowls, ducks, pigs and cattle. The question at issue is: How often does meat responsible for food poisoning come from obviously diseased or from apparently healthy animals? That *Salmonella* may give rise to acute disease in domestic animals is abundantly clear. Elkeles (1930), who has reviewed the subject, quotes figures from Standfusz which show that, of clinically recognizable infections, 22–47 per cent. are characterized by gastro-intestinal symptoms, 11–21 per cent. by septicæmia, 11–19 per cent. by disturbances occurring at parturition, and 19–48 per cent. by other manifestations. It seems probable that meat from such animals is far more likely to be dangerous to human beings than meat from animals which are suffering from no more than a latent infection of the glands or spleen. This is in accordance with epidemiological evidence, which shows that in most instances of food poisoning due to the consumption of flesh from an infected animal, the animal has been "emergency-slaughtered." In Germany, such animals afford a frequent source of human infection. No fewer than 120 of the German outbreaks recorded by Meyer (1929) between the years 1923 and 1928 were due to this cause. In Great Britain and the United States, on the other hand, the consumption of meat from obviously sick animals is far less common, and most salmonella food-poisoning outbreaks are due to contamination of meat from a healthy animal after slaughter. Exceptions do, however, occur. Animals that appear to be healthy in the abattoir may nevertheless be suffering from a generalized salmonella infection. Scott (see Report 1936), for example, records an outbreak traced to the carcase of an animal that was almost certainly suffering from septicæmia. The carcase was not noticeably unhealthy, yet from all parts of it *Salm. typhi-murium* was isolated. Ketz (1937) likewise describes an outbreak due to the same organism which was traced to the meat of a young cow. This animal had been inspected by the veterinarian before slaughter and had been reported as in prime condition. No evidence of disease was found on examination of the carcase, but *Salm. typhi-murium* was isolated from a number of animals on the farm from which the cow came. Healthy carriers of this sort are probably uncommon, but it is well to remember that neither they nor the very early septicæmic case can be detected by veterinary inspection. A further exception must be made for certain milk-borne outbreaks in which, either the udder of the cow is shown to be infected, or the milk becomes contaminated

from the infected fæces of the animal. Outbreaks of the former type have been recorded by Kinloch, Smith and Taylor (1926) and Tulloch (1939), and of the latter type by McAllan and Howie (1931) and Conybeare and Thornton (1938).

Passing on to the second method of infection, we may note that opportunities for sound meat to be contaminated during the course of preparation for food are numerous, though it is notoriously difficult to detect the way in which any given article has been infected. The main sources are rats and mice, and human carriers.

The frequency of rodent typhoid varies in different countries, and in different parts of the same country, and is often increased locally by the use of " virus " preparations containing living salmonella organisms for the extermination of rats and mice. It is well known that infected animals, while suffering from a chronic disease, or showing no obvious symptoms of illness, may excrete the causative organism in the fæces for weeks or months (Topley and Ayrton 1924). Moreover, in the fæces themselves, *Salmonella* may survive under favourable conditions for 5 months or longer (Welch *et al.* 1941). Food prepared in unsanitary premises is liable to be contaminated from the droppings of these animals. It is usually difficult to obtain conclusive evidence that the food has been infected in this way, but outbreaks suggestive of a rodent source of infection have been described by Bainbridge (1912), Willführ and Wendtlandt (1921), Spray (1926) and Jones and Wright (1936). In addition, several outbreaks are on record in which infection has been traced, directly or indirectly, to the use of " virus " preparations (see Shibayama 1907, Jordan 1931, Kristensen and Bojlén 1931, Harhoff 1941, Leslie 1942).

The part played by the *human carrier* is difficult to define. In 121 outbreaks of food poisoning investigated by Savage (1932) there were only 5 in which a human carrier seemed to have been responsible, and Savage would therefore ascribe little importance to this mode of infection. Other workers, however, such as Jordan (1917) and Geiger (1923) take a more serious view. Rubenstein, Feemster and Smith (1944) ascribed no fewer than 6 out of 17 food-poisoning outbreaks to infection by human contact. There are now numerous instances on record in which *Salmonella* has been isolated from convalescents, ambulant cases, chronic carriers, and healthy persons.

Thus Fletcher (see Perry 1920) found *Salm. typhi-murium* in the fæces of three soldiers who were convalescing from dysentery or enteric fever. Trommsdorf, Rajchman and Porter (1911), in their investigations of the Wrexham outbreak of 1910 due to pork pies, found that the head cook was a chronic carrier, and was excreting an organism of the *Salmonella* group in her fæces. Sporadic cases of infection with organisms of the *Salmonella* group are not uncommon (Rosher and Wilson 1921). A large outbreak of food poisoning in France during the war of 1914–18 due to *Salm. newport* was ascribed by Perry and Tidy (1919) to a human carrier in the cook-house.

Borman, Wheeler, West and Mickle (1943) encountered one carrier of *Salm. bareilly* and another of *Salm. worthington*—both of over a year's standing. Moreover, now that routine examinations of canteen staffs are common practice, and methods of isolation have been improved, far more salmonella carriers are being detected than formerly. Thus Borman and his colleagues found two patients at operation to be carrying *Salm. montevideo* in the gall-bladder. Bornstein, Saphra and Strauss (1941) met with healthy carriers of the *oranienburg, derby, typhi-murium, chester* and *montevideo* types—three of them in food handlers ; and Bornstein and Saphra (1942) reported the finding of healthy carriers of the *urbana* and *senftenberg* types. Four chronic carriers were met with by Rubenstein, Feemster and Smith (1944). Patients who have suffered from salmonella infection may

continue to excrete the causative organism for several weeks. Perry and Tidy (1919), for example, reporting on an outbreak in France affecting over 1,000 men, due to *Salm. typhi-murium*, found that 50 per cent. of the patients ceased to excrete the organisms by the end of the 4th week; one patient, however, was still excreting them after 14 weeks. Mosher, Wheeler, Chant and Hardy (1941) report that in another outbreak, due to *Salm. typhi-murium*, about 50 per cent. of the convalescents excreted the organism in the fæces for 2 weeks, 20 per cent. for 4 weeks, 10 per cent. for 7 weeks, and occasional patients for even longer, one continuing for 18 weeks. The experience of the Emergency Public Health Laboratory Service in England and Wales during the second world war amply confirmed these findings, and several patients were encountered who had been excreting *Salmonella* in the fæces for many months. Numerous workers, it may be noted, have found *Salmonella* in the *tonsils*. Varela and Olarte (1942), for example, in Mexico, isolated organisms of this group belonging to 8 different species from 8 per cent. of hypertrophied tonsils removed from children.

Temporary carriers and ambulant cases must always be a menace to the human population. Their detection by bacteriological methods is bound to be difficult, since their infection will often have cleared up before suspicion is cast upon them. How far the chronic human carrier is responsible for infection of food must, however, await further observation.

It may be noted that, in food-poisoning outbreaks due to food derived from a sick animal, *Salm. enteritidis* and *Salm. dublin* are most frequently found, whereas in outbreaks due to sound meat contaminated during its course of preparation for food, *Salm. typhi-murium* is the predominant organism (see Bainbridge 1912, Mayer 1913, Jordan 1917).

Before leaving this subject attention should be drawn to the apparent infrequency of salmonella food poisoning in man in spite of the widespread incidence of infection in domestic animals, and their products used for food, and in rodents. Scott (Report 1929) explained this discrepancy on the assumption that large doses of *Salmonella* were probably required for infection of man. In typhoid, cholera and probably dysentery, minute amounts of infective material may suffice to cause disease; but in food poisoning large doses are generally necessary. Savage (1942*a*) has ably developed this theme in relation to paratyphoid fever; and Hormaeche, Peluffo and Aleppo (1936) have supported it by human volunteer experiments with *Salm. typhi-murium*. These workers found that adults might ingest as many as 2,000 to 4,000 million organisms without suffering from any symptoms at all, or from not more than mild afebrile diarrhœa. Infants and old persons, however, appear to be considerably more susceptible, and fatal cases are restricted mainly to these two age groups.

Bacteriology and Epidemiology of the Toxin Type of Food Poisoning

The clinical manifestations of this type of food poisoning, which come on usually after a very short incubation period, have already been described. The type of food concerned varies considerably. Canned or potted meat or fish, meat pies, gravy, pickled or pressed beef, ham, tongue, and cream or custard fillings are among the commonest articles, but cheese, ice-cream and milk are occasionally incriminated. Numerous outbreaks in this country have followed the consumption of imported American spray-dried egg.

Our knowledge of this form of food poisoning is still fragmentary, mainly owing to the absence of any laboratory test for demonstrating toxin in the food or in bacterial cultures prepared from it. The cause of one form, however, is

now established without any reasonable doubt, namely that due to staphylococcal enterotoxin.

Staphylococcal Toxin Poisoning.—As Dack (1943) points out, the ability of some strains of staphylococci to produce a toxic substance capable of irritating the gastro-intestinal tract has been discovered four times—by Denys (1894) in Belgium, by Owen (1907) in the United States, by Barber (1914) in the Philippines, and by Dack, Cary, Woolpert and Wiggers (1930) in the United States. In 1914 Barber, working in the Philippines, reported a very clear instance of a "toxin" outbreak due to the growth of a white staphylococcus in the milk of a certain cow. Immediately after withdrawal from the udder, the milk could be consumed with impunity, but if it was allowed to stand for a few hours at room temperature, 28°–30° C., it gave rise within about 2 hours to nausea, vomiting, abdominal pain, diarrhœa, cramps, and faintness. Similar symptoms were produced in human volunteers by the consumption of pure milk cultures of the strain of *Staph. albus* isolated from the cow in question, though kittens, puppies, and monkeys proved refractory. This report furnished in its general outlines an almost complete picture of the causative factors responsible for a "toxin" outbreak. Unfortunately, however, no particular attention seems to have been paid to it, and it was not till the rediscovery several years later by Dack and his colleagues (1930) of staphylococcal food poisoning that the subject attracted the attention it deserved. Since that time numerous outbreaks caused by the production of a toxic substance elaborated by staphylococci in the food have been described (Dack *et al.* 1930, 1935, Jordan 1931, Jordan and Hall 1931, McBurney 1933, Jordan and Burrows 1934, Report 1934). Most of the outbreaks have followed the consumption of milk products, particularly cakes and éclairs filled with cream or custard, though some have been traced to gravy or to canned meat or fish. The circumstances have invariably been such as to favour the multiplication of the organisms in the food prior to its consumption.

The origin of the staphylococci is still in doubt, but in view of the frequency of these organisms in the human nasopharynx, on the human skin, and in cows' milk, contamination of food must be relatively common. Only, however, when conditions favour their growth in the food, is their presence likely to be of danger. What proportion of strains are toxigenic is not yet known. Hope of settling this point and of learning something about the conditions that favour the formation of enterotoxin was awakened by the introduction by Dolman, Wilson and Cockcroft (1936) in Canada of the intraperitoneal kitten test.

These workers found that, if a suitable strain of staphylococcus was grown in soft nutrient agar for 3 days at 37° C. in an atmosphere containing 10 per cent. CO_2, an enterotoxin was produced which, when extracted by saline and inoculated intraperitoneally into a kitten, gave rise to vomiting within about 2 hours. To avoid confusion, any hæmolysin present had to be inactivated by neutralization with specific serum, by formolization, or by boiling for 20 minutes at pH 7. Unfortunately, this method has not withstood the test of experience. The observations of Kojima and Kodama (1939), Slanetz (1942), and Fulton (1943) strongly suggest that the substance responsible in the boiled extract for causing vomiting is residual β-toxin. Fulton, for instance, was able to obtain a positive kitten response with as little as 2 μg. of a purified β-lysin. On the other hand, the β-lysin is apparently incapable of causing gastro-intestinal irritation in man (Fulton 1943, Dolman 1943). This may explain why extracts of staphylococcal cultures from some toxin outbreaks have given a negative kitten test, and why extracts of other

strains from non-epidemic sources have caused vomiting in kittens but have proved innocuous to human volunteers. Whether it is possible, as Dolman (1943) maintains, to distinguish the reaction of the kitten to enterotoxin from that due to β-lysin is doubtful; further work will be required to settle this point. Several other animal tests for detecting enterotoxin have been described (see p. 617), but none of these has so far been entirely satisfactory. In 1935 Stritar and Jordan concluded that no method existed, apart from the feeding of broth filtrates to human volunteers, of determining whether a given strain was toxigenic. With this conclusion we are still forced to agree.

Little is yet known about the nature of the toxin produced. Dolman has always insisted that it is distinct from either the α or the β-hæmolysin; but though it is now fairly well established that it cannot be identified with the β-lysin, its lack of relation to the α-lysin is not so clear. Fulton (1943) was unable to separate the two, and was of the opinion that some, though not all, α-lysins might be enterotoxic.

Reference has already been made to the apparently curious behaviour of the enterotoxin towards heat. The evidence suggests that, in common with the α and β-staphylococcal lysins, the lecithinase of *Cl. welchii* cultures, and probably certain other substances of enzymic nature, the enterotoxin may be inactivated by heating at 60° C. for 30 minutes, but may not be completely destroyed by boiling (see Fulton 1943). Confusion has arisen in the past owing to failure to realize this, and to the statement frequently made that the α-lysin is destroyed at 60° C., whereas the enterotoxin withstands heating to 100° C. (see pp. 615–617).

The enterotoxin gives rise to acute gastro-enteritis with severe collapse when consumed by human volunteers in doses of 2–10 ml., but different persons vary in their susceptibility towards it. It is relatively non-toxic when fed to most laboratory animals, though young *rhesus* monkeys may be affected after a dose of 25–50 ml. It is of doubtful antigenicity, and little tolerance to it seems to be developed in the human subject as the result of repeated dosage (see Jordan 1930, Jordan, Dack and Woolpert 1931, Dack, Jordan and Woolpert 1931*a*, Dack *et al.* 1931*b*, Jordan and Burrows 1933); though Dolman (1944) claims to have been able to immunize human subjects against it by repeated subcutaneous injections of a formol toxoid preparation.

Non-staphylococcal Toxin Poisoning.—The occurrence of staphylococcal food-poisoning outbreaks has suggested an explanation for many of the other "toxin" outbreaks. For several years banal organisms such as *Proteus vulgaris* and *Bact. coli* have been found in suspected food, but their importance has generally been discounted on the basis of their non-pathogenicity to laboratory animals. It is now becoming increasingly probable, both on epidemiological and bacteriological grounds, that a number of organisms, many of them non-pathogenic, when allowed to grow in food under suitable conditions, are able to give rise to toxic substances having a highly irritating effect on the human gastro-intestinal mucosa.

Numerous outbreaks have now been described in which no living *Salmonella* or *Shigella* could be demonstrated, but in which the incriminated food contained large numbers of organisms belonging to the *Proteus*, coliform, *Streptococcus*, or aerobic spore-bearing groups (see, for example, Glücksmann 1899, Silberschmidt 1899, Pfuhl 1900, Aoki and Sakai 1926, Linden, Turner and Thom 1926, Demnitz 1926, Jansen and Dooren de Jong 1930, Cary, Dack and Myers 1931, Gustafson 1932, Tanner and Ramsey 1932, Jordan and Burrows 1934, Gray 1937, Cary, Dack and Davison 1938, Kathe 1937, Scott 1939, Lodenkämper 1940, Cooper,

Davies and Wiseman 1941, Getting, Rubenstein and Foley 1944). Dolman (1943) is of the opinion that many, if not all, outbreaks of this type are really due to staphylococcal enterotoxin, formed by staphylococci that have subsequently died out or been overgrown by other organisms. Such a unitarian hypothesis, however attractive, is not altogether satisfactory. We have ourselves examined a number of foods from toxin outbreaks in which we have been unable, even by the use of enrichment and selective media, to demonstrate a single staphylococcus, or to detect the presence of pre-formed staphylococcal hæmolysin in an extract of the food. It is not easy to explain why a hardy organism like *Staph. aureus* should die out completely, when less resistant organisms like green-producing streptococci are present in abundance. Again, in some of the toxin outbreaks, the incubation period has been as long as 12 hours; in known staphylococcal outbreaks, on the other hand, it is usually 1–4 hours, and rarely, if ever, longer than 6 hours.

Whether the other organisms, to which we have referred, are able to form a true enterotoxin, whether they produce toxic breakdown products in the medium, or whether they act in some other way is still unknown. The observations of Cary and his collaborators (1931, 1938) suggest that green-producing streptococci may give rise to food poisoning when they are ingested in large numbers *alive*, but that they do not produce filtrable toxic substances *in vitro*. If this is true, it is difficult to understand why, in some of the streptococcal outbreaks that have been described, the incubation period has been as short as 4 hours, for little toxin production by living bacilli could be expected in so short a time.

Experimental work on the non-staphylococcal types of food-poisoning has not been fruitful.

Jordan and Burrows (1935) reported that freshly isolated strains of organisms such as streptococci, *Proteus*, *Bact. coli* and *Bact. ærogenes*, when grown under suitable conditions, were capable of producing substances that caused vomiting and other symptoms of gastro-intestinal irritation in monkeys. The exact conditions necessary to the production of these substances were not defined, but growth in a custard medium, or in a medium to which starch had been added, appeared to be particularly favourable. Hunter and Dack (1938) were unable to confirm these findings; and Dolman (1943) has likewise failed to produce vomiting in human volunteers fed with culture filtrates of strains of *Proteus vulgaris*, *Bact. coli*, streptococci and aerobic spore-bearing bacilli that had been isolated some months previously from suspected food. Negative results of this sort are always difficult to interpret, and it may well be that only some strains are toxigenic or toxigenic only under certain conditions. The question is still open, and calls for further investigation.

Whether organisms of the *Salmonella* group can produce enterotoxic substances is likewise open to dispute. There is plenty of evidence to show that they contain in their bodies thermostable, water-soluble substances which are toxic on parenteral inoculation into animals (Brieger and Fraenkel 1890, Cathcart 1906*a*, Ecker 1917, Savage and White 1925*a*, Menten 1926, Bahr and Dyssegaard 1927, Meyn 1930). Methods for extracting these bodies have been described by Boivin and Mesrobeanu, Raistrick and Topley, and Morgan (see Chapter 44), who have shown that they are of polysaccharide nature. Injected intravenously into rabbits, they give rise to great weakness and prostration, often accompanied by tremors, diarrhœa, and hyperglycæmia (Delafield 1934); and injected intraperitoneally into mice in a dose of about 0·5 mgm., they prove fatal (Martin 1934). But there is as yet no conclusive evidence that they are able to cause gastro-enteritis in man when taken by the mouth. Feeding experiments carried out on human volunteers and on

monkeys by Dack, Harmon and Jarra (1928), Dack, Cary and Harmon (1928), and Verder and Sutton (1933), using heat-killed organisms or culture filtrates of *Salm. typhi-murium* and *Salm. enteritidis*, proved uniformly negative. Moreover, the ingestion by students of even 200 mgm. of the polysaccharide fraction isolated by Raistrick and Topley (1934) from *Salm. typhi-murium* was without any obvious effect (Colbeck 1942).

Summarizing, we may say that many of the " toxin " outbreaks of food poisoning appear to be due to the production of toxic substances in the food prior to its consumption. That some strains of staphylococci are capable of forming a potent enterotoxin, there is no doubt. Whether other bacteria, particularly streptococci, coliform bacilli, *Proteus*, and aerobic spore-bearers, are able under favourable conditions to render food toxic is still undecided. There is ample scope for investigation along these lines.

The frequency of the toxin type of outbreak varies in different countries. Table 148 (p. 1594), which shows the figures for England and Wales, almost certainly underestimates, and underestimates grossly, the real incidence of the disease. The attack, though often violent, is usually over so soon, and is limited so frequently to a few persons that the health authorities get to hear of only a small proportion of the total cases. Scott (1936) estimates that probably about one-third of the reported outbreaks of food poisoning of the toxin type are due to staphylococcal intoxication, but our information is as yet too scanty to justify us in making any definite statement. One factor that greatly hinders exact knowledge on this subject is the absence of any simple laboratory method for detecting the presence of toxic substances in the food or in filtrates of broth cultures of suspected organisms. For this reason many bacteriological reports are completely negative, and no further attention is paid to the outbreaks. One fact does seem clear, namely that poisoning due to canned meat and fish is becoming much less common in this country, owing apparently to the improvements in processing made during recent years (Savage 1939). Another interesting fact is the comparative infrequency now of summer diarrhœa of infants. Though this condition is usually of an infectious nature, there is a good deal of evidence to suggest that milk in which inordinate bacterial growth has been allowed to occur may contain substances having an irritating effect on the gastro-intestinal mucosa, particularly of infants. Attention was drawn to this possibility many years ago by Park and Holt (1903). There is reason to believe that one factor in the diminution of summer diarrhœa of late years has been the much greater care exercised in the production of milk, and the frequency with which it is now submitted to pasteurization or other forms of heat treatment.

Diagnosis and Investigation of Outbreaks.

The diagnosis of food poisoning is primarily clinical. For the full investigation of an outbreak the reader is referred to textbooks of Hygiene, but the general procedure is briefly as follows: (1) Secure a complete list of cases. (2) Obtain particulars of individual cases. (3) Ascertain the vehicle of spread. (4) Determine the causal agent—chemical irritant, *Salmonella*, *Shigella*, *Cl. botulinum*, staphylococcal toxin, or other form of toxin or infection. (5) Find out how the vehicle became infected. (6) Endeavour to trace the reservoir from which the vehicle became infected, such as rodents, cattle, fowls, ducks, or human carriers (see Savage 1942*b*).

Materials collected for examination should include (1) the actual food consumed ; it is most important that this should be obtained : (2) the vomit and fæces of patients, and the blood for agglutination : (3) the blood, spleen, liver and intestine of fatal cases : (4) the fæces and blood of suspected carriers who may have contaminated the food. The material should be sent to the laboratory packed in ice. A bacteriological examination should first be made, and if this is negative, search should be made for chemical poisons or preservatives in the food.

In salmonella outbreaks the organisms can frequently be demonstrated in the food, and in the fæces of the patient ; vomited matter is much less satisfactory. In their isolation the general plan should be to plate suspensions of the suspected material on to suitable selective and differential media (see Chapter 69 and Felsenfeld 1944), both directly and after incubation in selenite or tetrathionate broth, to pick off likely colonies, to identify them roughly by the slide agglutination method using special group sera, and to complete their identification later by cultural, biochemical, and more detailed serological methods.

For a description of the general mode of investigating food-poisoning outbreaks and of identifying salmonella types, reference should be made to a memorandum by the Ministry of Health (Memo 1935), to Kauffmann's (1941) monograph, and to a paper by Edwards and Bruner (1942) ; and for rapid methods of detecting certain chemical poisons to a paper by Korff and Kaplan (1942). The occurrence of uncommon types of *Salmonella* often affords a strong indication of the probable vehicle or reservoir of infection ; and even with some of the commoner types, such as *Salm. typhi-murium* or *Salm. enteritidis*, antigenic or biochemical peculiarities may be of help in this respect. For example, absence of the V somatic antigen from *Salm. typhi-murium* suggests a pigeon source (Edwards and Bruner 1940), and the biochemical characters of the *danysz* sub-type of *Salm. enteritidis* are indicative of a rodent origin. Even more promising is the application of the bacteriophage method of typing. Felix and Callow (1943) have already been able to distinguish two types of *Salm. typhi-murium* by this means, and it is hoped that further progress along these lines will be made. The length of time during which *Salmonella* can be isolated varies considerably. Reference to p. 1604 will show that about 50 per cent. of patients continue to excrete the causative organism for 2–4 weeks. It is therefore always worth while attempting to make a retrospective diagnosis by examination of the fæces of convalescents. It must be remembered that occasional outbreaks of suspected food poisoning are caused by members of the dysentery group—especially *Sh. flexneri* and *Sh. sonnei*.

Suspected material may be inoculated into mice or guinea-pigs, but this procedure is liable to cause confusion. Laboratory rodents often suffer from natural infection with the very types of *Salmonella* that are most likely to be found in cases of food poisoning. In consequence, bacilli may be isolated from the tissues other than those contained in the inoculum. Many careful workers have fallen victim to this type of occurrence (Holth 1909, Mühlens *et al.* 1909, Zwick and Weichel 1910). A similar technique applied to the fæces of healthy animals such as cattle and pigs has also been responsible, it may be noted, for grossly misleading reports on the frequency of salmonella bacilli in normal excreta. Unless therefore a stock of animals is available which is known to be free from this type of infection, it is advisable not to use the animal inoculation method.

An indirect method, which may sometimes be of help in diagnosis, is afforded by the use of the agglutination test on the sera of the patients. The value of this

method, however, is seriously diminished by the fact (1) that the agglutinin response in infected persons is usually poor and is often absent, and (2) that salmonella agglutinins may be present in the sera of healthy persons (see Chapter 69). In patients who have suffered from enteric fever or from previous salmonella infection, or who have been inoculated with T.A.B.C. vaccine, residual agglutinins may be present; and a rise in titre within ten days or a fortnight of the food-poisoning attack may be due to an anamnestic reaction. Even if agglutinins are found in fairly high titre, they can afford no more than an indication of the antigenic group to which the infecting organism belongs. In practice it is usually sufficient to test the serum of the patients against the species of *Salmonella* that are known to be commonest in the region, choosing preferably chloroformed suspensions giving both H and O agglutination (Scott 1936; see also Bridges and Taylor 1944). Of more value epidemiologically is the testing of the serum against the infecting organism itself, if this has been isolated from one or more of the patients. In this way useful information may sometimes be obtained about the possible connexion of suspected cases or carriers with the main outbreak. But again, a negative result is of little value, since so many patients fail to develop agglutinins.

In the absence of demonstrable salmonella or dysentery infection, or of symptoms pointing to chemical poisoning, an endeavour should be made, particularly in outbreaks of the toxin type, to obtain evidence of the presence of toxic substances of bacterial origin in the food or of organisms capable of forming such substances. The investigation of this type of outbreak is remarkably difficult. Though it may be worth while feeding the suspected material to *rhesus* monkeys, the only satisfactory way is to make tests on human volunteers. Search should be made in the food for organisms such as staphylococci, streptococci, coliform, *Proteus* and aerobic spore-bearing bacilli, which may be potentially toxigenic; but little attention should as a rule be paid to any of these organisms unless it is present in large numbers. Similar organisms should be sought for in the patient's excreta. In staphylococcal outbreaks, the organisms may be found in the vomit and occasionally in the fæces; if so, they should be examined serologically or by the bacteriophage typing method (see Wilson and Atkinson 1945) to see whether they resemble the strain isolated from the food. Any organism on which serious suspicion is cast should be grown in soft agar for 2–3 days in 10–30 per cent. CO_2, and a saline extract of the culture, filtered or centrifuged to remove living organisms, fed in 2–5 ml. quantities to human volunteers.

In many of these outbreaks even a careful review of all the evidence, epidemiological and bacteriological, will justify no more than a cautious expression of opinion as to their mode of origin. As has already been pointed out, there is ample scope for investigation of this type of outbreak, and it is to be hoped that in the future an attempt will be made to ascertain the chemical nature of the bacterial toxins found in the food.

The examination of canned foods should be conducted on the same principles as that of fresh food, but there are a number of technical details to be attended to; for a description of these the reader is referred to articles by Esty and Stevenson (1925), Savage (1923), Esty (1935), Woodcock and Lewis (1938), Jones and Jones (1941), Report (1941), and Baumgartner (1943).

Prophylaxis.

The hygienic precautions necessary to prevent food poisoning concern the whole course of the food from the slaughter of the animal to the final preparation

for consumption. A thorough system of meat inspection is essential. The meat of animals that are ill or are emergency-slaughtered should as a rule be condemned. To this precaution alone Meyer (1916) attributes the comparative infrequency of meat poisoning in California, where it is known that calves are infected with *Salm. enteritidis*. The laxity of the meat inspection in Germany since the war of 1914–18 appears to have resulted in a great increase in the number of poisoning outbreaks. The measures to be taken to ensure the cleanliness of premises where made-up meat is prepared are dealt with fully in textbooks of Hygiene. Valuable control measures, affecting both equipment and personnel, are suggested in the Ordinance and Code of the United States Public Health Service regulating eating and drinking establishments (Report 1943). It is particularly important not to employ cooks having a history of previous enteric infection. Any food-handler suffering from vomiting or diarrhœa should be suspended from work or given other occupation. Everything should be done to prevent the access of rats, mice, flies (see Ostrolenk and Welch 1942), and other animals or insects to food destined for human consumption.

Meat should be used fresh whenever possible, and should be thoroughly cooked before it is eaten. Cooking, it must be understood, does not necessarily sterilize the meat. The penetration of heat into a large joint is slow, and the interior may not reach, or may not be maintained long enough at, a temperature sufficient to kill all the organisms. This is especially true of food contained in cans, which, even after heating to above the boiling-point for an hour or more, may yet contain living organisms—generally thermophilic or spore-bearing bacilli or resistant micrococci. Several workers have shown that about 70 per cent. of samples of canned foods are not sterile (Vaillard 1902, Bushnell 1922, Savage 1923). On the other hand, food poisoning is far less often caused by canned foods than by made-up foods. This is to be attributed partly to the greater heating that the former receive, but largely to the much greater care that is used in their preparation. But cooking is a wise precautionary measure; even if it fails to kill all organisms, it probably succeeds in diminishing their numbers. If the food is not to be eaten immediately after it has been cooked, it should be placed in a cool situation, preferably in an ice-chest; otherwise organisms that have escaped destruction may multiply abundantly. That this is true is manifested by the Chesterfield outbreak, which was due to the consumption of pork pies. In persons who ate them 2 days after they had been cooked, the incubation period was 22 hours; in those who ate them 4 days after cooking it was 20 hours; 6 days after cooking it was 14 hours, and 7 days after it was only $2\frac{1}{4}$ hours, suggesting that the organisms had multiplied abundantly since the preparation of the pies (see also Baars 1931). This precaution applies to all foods, especially milk. After pasteurization or boiling the milk should be rapidly cooled. In the preparation of ice-cream Buchan (1910) found that an enormous increase of bacteria occurred during the process of slow cooling that is employed after the preliminary heating.

The protection of custard and cream fillings and of made-up meat dishes, such as brawn and pressed beef, from staphylococcal infection of human origin requires the greatest care and vigilance. In heavy nasal carriers of *Staph. aureus*, the hands are often infected, and there may be suppurative skin lesions on the hands and arms. Measures little short of a surgical aseptic technique may have to be taken to prevent infection of the ingredients, and stringent regulations should be laid down about the adequate heating and subsequent refrigeration of the food.

The consumption of any animal food in the raw condition is attended by a certain amount of risk. This is particularly true of milk and cream. There is general agreement that, for the prevention of food poisoning and other milk-borne diseases, these articles should be submitted to pasteurization or other adequate form of heat treatment.

BOTULISM

Introductory

Botulism (from Latin *botulus*, a sausage), sometimes known as allantiasis, or ichthyosismus, is a disease that was first described in 1820 by the German poet and medical writer Justinus Kerner (Jordan 1917). The causative bacterium was isolated and described by van Ermengem in 1896 (1896, 1897). Following on a festive gathering of a music club at the village of Ellezelles in Belgium, several of the members were taken ill, and three of them died within a week. The disease was confined to those who had partaken of a certain piece of raw ham; the other ham and the remainder of the animal had been previously consumed without causing trouble. The contaminated ham, which was paler and softer than normal and smelt rancid, had during the process of pickling been placed at the bottom of the vessel and had come into contact with the brine. When fed to cats it caused mydriasis, partial paresis, secretory disturbances, aphonia, and other symptoms. From it van Ermengem cultivated a strictly anaerobic organism, which secreted a powerful toxin, giving rise to the same symptoms in cats as those caused by the original ham.

Since that date several outbreaks of botulism have been recorded, some in Germany, but more in America, where of late years the disease has attracted general attention. In this country only four small outbreaks have been described. (See p. 1614.)

Symptomatology and Pathology.

The incubation period is generally under 24 hours after consumption of the affected food, but may be prolonged to 72 hours. Prominent among the symptoms are vomiting, constipation, ocular pareses, thirst, pharyngeal paralysis, the secretion of thick, viscid saliva, and sometimes aphonia. General consciousness and sensibility remain intact till near the end, which is preceded by coma or delirium. The temperature is generally subnormal—96–98° F. Later in the illness it may rise owing to the onset of broncho-pneumonia (Dickson 1918). Death may occur within 24 hours from the time of onset, or may be delayed for a week. In cases that survive, complete recovery, particularly of the ocular movements, may not take place for 6 or 8 months. At autopsy the kidneys, liver, and meninges are congested. Histological examination of the organs may reveal the presence of thrombosis.

How the toxin acts is still under dispute. Kempner and Pollack (1897), Marinesco, and several of the earlier workers found changes in the nerve cells of the brain and spinal cord of animals dying from *botulinum* poisoning. The work of Dickson and Shevky (1923) and Cowdry and Nicholson (1924), on the other hand, suggests that the main effect of the toxin is exerted on the peripheral nerve endings, possibly those of the autonomic system. More recent observations by Bishop and Bronfenbrenner (1936) point likewise to the myoneural junction

as the main point of attack, the toxin behaving like curare in paralysing the nerve endings. Contrary to the findings in tetanus, there appears to be no fixation of the toxin by the brain tissue (Coleman 1924).

Bacteriology.

Botulism is an intoxication, not an infection. The causative organism, *Cl. botulinum*, multiplies in the food before it is consumed, and produces a powerful soluble toxin, which on ingestion is absorbed by the mucosa of the stomach and upper part of the intestine, and gives rise to the characteristic disease. The potency of this toxin is such that the fatal dose for an adult man, calculated on the basis of animal experiments, might be as small as 1/100 mgm. or even less (Bengtson 1924). The smallest lethal dose of the strongest tetanus toxin that has yet been prepared is about 25 times as great as this. Its ability to pass through the gastric mucosa unchanged distinguishes it from tetanus or diphtheria toxin, both of which are harmless when given by the mouth. This may be due partly to its resistance to acids ; in an alkaline medium, such as prevails throughout the greater part of the small intestine, it is unstable. Of the two main types of *Cl. botulinum* that have been encountered in human botulism, Type A is much commoner than Type B ; thus in 23 outbreaks occurring in the United States, 19 were due to Type A, and only 4 to Type B (Editorial 1926). Two fatal cases due to Type E have been described in the United States, one following the consumption of German-canned sprats, the other of smoked Nova Scotia salmon (Hazen 1938).

Though the disease is essentially an intoxication, evidence has been accumulating that under certain conditions the organism may multiply to a limited extent in the animal body. It is not necessary to examine this evidence in detail, but briefly it has been found (Edmondson *et al.* 1920*b*, Orr 1920, 1922, Coleman and Meyer 1922, Graham and Eriksen 1922, Coleman 1923, Hall and Davis 1923, Starin and Dack 1925) that if spores, which have been freed of their toxin by repeated washing or by heating to 80° C. for half an hour, are injected subcutaneously into guinea-pigs in large doses—500 million or so—or are given by the mouth in still larger doses—about 2,000 million—they may give rise to fatal disease ; from the spleen, liver, kidneys, or mesenteric glands the bacilli may be recovered in pure culture after death. The experiments on which these findings are based are not very convincing ; doubtless after such massive doses the spores are disseminated throughout the body. But it is doubtful whether germination of the spores occurs or whether the resultant bacilli multiply and form toxin. Since it is extremely difficult to free spores completely from all traces of toxin, especially by washing, and since very small quantities are required to kill a guinea-pig—1/10,000 mgm. or less—it is not surprising that some animals injected with so-called toxin-free spores succumb to the disease.

Even if it is possible experimentally to reproduce a true infection with *Cl. botulinum*, there is no evidence that under natural conditions the disease in man is other than a pure intoxication. In this view the majority of authors strongly concur (van Ermengem 1897, Römer 1900, Armstrong *et al.* 1919, Burke *et al.* 1921, Geiger *et al.* 1922).

A disease closely simulating botulism in man can be reproduced by the experimental inoculation or feeding of cats, monkeys, and certain other animals with toxic material (see Chapter 36).

Epidemiology.

Botulism is due to the consumption of food in which *Cl. botulinum* has been growing. It occurs therefore in sporadic outbreaks limited to those who have

partaken of the contaminated food. Since the disease is an intoxication, not an infection, secondary cases do not occur, but it is common for cats, dogs, and especially chickens that are fed on the remnants of the food to develop symptoms of poisoning.

Botulism is not a common disease. From 1899 to 1925, 146 outbreaks were reported in the U.S.A. and Canada, affecting 504 persons; of these 337 died—a case mortality of 67 per cent. (Editorial 1926). Bacteriological evidence of the nature of the disease was available in 53 of these outbreaks. These figures probably underestimate the incidence of the disease; at any rate it appears to have become commoner during the last few years when greater attention has been focussed upon it. During the 8 years 1918–25 in the U.S.A. there were about 13 outbreaks per annum.

In Germany 24 outbreaks of suspected botulism were reported between 1907 and 1923, but in only one of these was *Cl. botulinum* isolated. In the British Isles only 4 outbreaks have been recorded, the largest of which occurred in 1922 at Loch Maree in Scotland, when 8 persons were attacked after eating potted duck paste; all the patients died within a week. *Cl. botulinum* Type A was cultivated from the remnants of the paste (Leighton 1923). The remaining three were in London. Two (Templeton 1935, Lane and Jones-Davies 1935), of which one was shown to be due to Type A, followed the consumption of vegetarian nut brawn. The third (Aitken, Barling and Miles 1936), which was due to Type B, occurred after eating a home-made meat pie. In America the disease is commoner during the winter months—the season of preserved food consumption.

Morbidity and Mortality Rate.—In any outbreak the morbidity rate is high. As a rule all who partake of the contaminated food develop the disease. The mortality rate varies in different outbreaks. In Germany it is said to be not more than 25 per cent. (Mayer 1913), but in America it is 60–70 per cent. (Burke *et al.* 1921). The earlier the symptoms appear, the higher is the mortality rate; of those that develop symptoms in 24 hours 84 per cent. die; of those that develop symptoms in 72 hours 55 per cent. die; and of those that are alive after the 8th day 20 per cent. die (Burke *et al.* 1921).

Type of Food.—Nearly all the reported outbreaks of botulism have been caused by food that has been smoked, pickled, or canned, allowed to stand for a time, and eaten before cooking, or after inadequate cooking (Jordan 1917). No cases have yet followed the consumption of fresh food, cooked or uncooked. In several instances those who have consumed the affected food after cooking have escaped, whereas those who have consumed it prior to cooking have been attacked (Geiger *et al.* 1922). There is a difference between Europe and America in the type of food responsible for poisoning. In Europe most cases have been due to sausages, ham, preserved meats, game pâtés, potted goose or duck, and brawn; a few, especially in Russia, have been ascribed to salted fish, such as salmon and sturgeon (van Ermengem 1897, Nitta 1919). In America, on the other hand, the contaminated foods have generally been canned fruits and vegetables, such as olives (Armstrong *et al.* 1919, Edmondson *et al.* 1920*a*), string beans (Geiger *et al.* 1922, Geiger 1924, Stricker and Geiger 1924), corn (Geiger *et al.* 1922, Geiger 1924), spinach (Geiger 1920), and peas (Editorial 1926). A few have been due to cooked meat or fish (Editorial 1926), and some to cheese (Nevin 1921). Home-canned string beans alone accounted for 19 out of 55 outbreaks in America (Editorial 1926).

In the majority of instances, the preserved foods have been noticeably spoiled.

The cans are often blown and show numerous gas bubbles on opening; the solid part of the food has a mushy or disintegrated appearance, and smells like rancid butter or cheese (Burke 1919*c*). In the case of ham the flesh is often paler and softer than normal, and has a rancid odour (van Ermengem 1897, Savage and White 1925*b*). The food, however, may be well preserved.

Mode of Infection of the Food and Distribution of Cl. botulinum in Nature.

The most extensive investigations on the distribution of *Cl. botulinum* in nature have been conducted by Meyer and his colleagues in America. It is abundantly clear that the organism is a normal inhabitant of the surface layers of the soil, from which it may obtain access to vegetables, fruits, hay, silage, and other cultivated produce. It may be transported by insects, and it may be eaten by horses, cattle, and other animals. In America it is common in the soils of the Western States of the Cordilleran system. It is less frequent in the Atlantic States, and is relatively rare in the Middle States, the Great Plains, and the Mississippi valley.

TABLE 150.

DISTRIBUTION OF *Cl. botulinum* IN DIFFERENT TYPES OF SOILS IN ALL STATES OF AMERICA, WITH THE EXCEPTION OF CALIFORNIA AND VIRGINIA.

Modified from Meyer and Dubovsky(1922*b*).

	Specimens Examined.	Toxic Cultures.	Weak Toxin.	Type A.	Type B.	Types A and B.
Virgin soil	335	105	22	59	22	2
Cultivated soils	274	47	13	18	16	—
Garden soils	142	41	12	23	6	—
Soil and manure from animal corrals and yards	161	20	9	6	5	—
Pasture	51	19	5	3	11	—

Tables 150 and 151, taken from Meyer and Dubovsky (1922*b*), illustrate the frequency with which it is encountered in different types of soils, and in vegetables and fodder.

In a similar study made of the soil and vegetable produce in California, 624 samples were examined; 206 yielded toxic cultures (Meyer and Dubovsky 1922*a*). Taking together the figures for the U.S.A. including California, Meyer and Dubovsky found that 581 of

TABLE 151.

DISTRIBUTION OF *Cl. botulinum* IN DIFFERENT VEGETABLES AND FODDER IN ALL STATES OF AMERICA, WITH THE EXCEPTION OF CALIFORNIA AND VIRGINIA.

Modified from Meyer and Dubovsky (1922*b*).

	Total No. Examined.	Positive Cultures.	Percentage of Positive Cultures.
Mouldy hay	44	7	15·9
String beans, pods and stalks	44	14	31·8
Decayed vegetation	29	6	20·6
Ensilage	15	3	20·0
Corn husks, leaves and stalks	80	6	7·5
Beets, roots and tops	37	6	16·2
Tomato plant and roots	24	2	8·3

2,162 samples examined showed the presence of *Cl. botulinum*, *i.e.* 26·8 per cent. Three hundred and ninety-five strains were typed; 250 or 63·3 per cent. were Type A, 138 or 34·9 per cent. were Type B, and 7 or 1·8 per cent. were mixed A and B.

From Table 150 it will be noticed that *Cl. botulinum* was commoner in virgin soils and pasture than in cultivated soils and manure. This has been held to indicate that the organism is a natural inhabitant of the soil and not merely a contaminant derived from animal fæces. Indeed the older view that the organism is a natural inhabitant of the intestine of animals, and is spread by their fæces, must be abandoned.

Meyer and Dubovsky (1922*c*) likewise examined specimens of soil from Belgium, Denmark, the Netherlands, England, and Switzerland. *Cl. botulinum* Type B was demonstrated in a variable proportion of soils from the different countries, but in not a single instance was Type A found. From this country 64 specimens were examined, and 9 of them yielded toxic cultures; the counties furnishing the positive results were Durham, Derbyshire, Middlesex, Hereford and Sussex, thus indicating a widespread distribution of the organism. In Scotland, Leighton and Buxton (1928), in an examination of 100 samples of soil, encountered *Cl. botulinum* four times; two of the cultures belonged to Type A, one to Type B, while the remaining one contained both Types A and B. Haines (1942), who examined 106 samples of soil from different parts of England—mainly the south-east—isolated *Cl. botulinum* with certainty from 5 per cent. Of the 5 strains, 4 came from grassland; 4 were Type A and 1 Type B. Both types of *Cl. botulinum* have been demonstrated in the soils of Canada, China, and at least one of the Pacific Islands (Dubovsky and Meyer 1922*b*, Schoenholz and Meyer 1922).

Meyer and Dubovsky's results have not as yet received general confirmation; some of their conclusions may have to be modified (Geiger and Benson 1923, Bachmann and Haynes 1924), and more work must be carried out before the relationship of the two types to environmental conditions can be definitely determined.

Cl. botulinum is present occasionally in the fæces of animals such as pigs, cattle, and horses (Burke 1919*a*, Tanner and Dack 1922, Easton and Meyer 1924), which feed on soil produce, but there is no evidence that it is a natural intestinal inhabitant. It is rarely present in the fæces of healthy human beings; Easton and Meyer (1924) failed to find it in 88 specimens examined, even though it was known that the spores were being ingested on raw fruits and vegetables used as food. Kahn (1924) likewise obtained negative results when examining the anaerobic flora of the stools of 72 persons.

Factors influencing the Development of Cl. botulinum in Canned Foods.—It is difficult to understand why, with such a wide distribution of *Cl. botulinum* in the soil and on fruits and vegetables, botulism itself is so uncommon. The organism is unable to grow in the animal body and give rise to infection; fresh foods, cooked or uncooked, may therefore be eaten with impunity. For botulism to result, the organism must multiply and form its toxin in the food before consumption. But even so one would expect the incidence of the disease from canned foods to be far greater than it is. We know that the spores of *Cl. botulinum* may withstand boiling for from half an hour to 22 hours (Bigelow and Esty 1920, Weiss 1921, Esty and Meyer 1922, Tanner and Twohey 1926), and a temperature of 120° C. for as long as 20 minutes. In the Loch Maree outbreak the potted duck paste had been heated during the process of manufacture at three different stages, the temperature in one stage approximating to 115° C. for 2 hours. Heat alone is therefore not sufficient to explain why the majority of canned foods are innocuous. Other factors must be concerned.

The hydrogen-ion concentration of the food has an important bearing on the efficacy

of sterilization. Esty and Meyer (1922) found that at pH 7·0 the spores were destroyed in 330 minutes at 100° C.; at pH 5·05 in 45 minutes, and at pH 3·7 in 10 minutes. The higher the hydrogen-ion concentration, the shorter is the time required for destruction (Bigelow and Esty 1920, Weiss 1921). The presence of sodium chloride in the food lowers the thermal resistance, which decreases with increasing concentration of the salt (Weiss 1921). The smaller the number of spores in the food the shorter is the time necessary to kill them (Bigelow and Esty 1920). Spores from young cultures are said to be more resistant to heat than those from old (Weiss 1921, Esty and Meyer 1922, Tanner and Dack 1922). These are some of the factors influencing the sterilization of the food.

It has also been found that spores of *Cl. botulinum* may remain dormant for days, weeks or months before germinating (Dickson *et al.* 1925). The type of food influences the development of the bacilli; string beans, spinach, corn, peas, and salmon appear to be specially favourable for growth; acid fruits and vegetables are less so (Koser *et al.* 1921, Geiger and Benson 1923, Schoenholz *et al.* 1923, Bachmann 1924). Below pH 4·5 germination is inhibited in most fruits. Such products can safely be processed in boiling water, whereas above pH 4·5 the processing must be sufficient to destroy even the most resistant spores (Esty 1935). Dissolved tin, such as results from the use of unlacquered cans, is said to inhibit growth (Scott and Stewart 1944). The presence of other organisms, such as *Cl. sporogenes*, apparently interferes with development (Jordan and Dack 1924). Finally, not all strains of *Cl. botulinum* form toxin (Bengtson 1922*b*) though the majority appear to do so (Starin 1924).

It is probable that a large number of factors determine the survival, germination, multiplication, and toxin production of *Cl. botulinum* in canned food. Unless these factors are favourably combined the food remains innocuous. The most important of these appear to be (1) the presence of spores in suitable numbers, (2) insufficient heating, (3) anaerobic conditions, (4) too slow cooking, (5) the use of the food without final cooking. The records make it clear that the danger from home-canned food is far greater than from that which is commercially prepared.

Given very favourable conditions, *Cl. botulinum* may produce detectable toxin within 12 hours, but usually it takes 2–14 days, depending on the temperature of storage of the food and other factors. According to Tanner and Oglesby (1936), and Tanner, Beamer and Rickher (1940), little or no growth occurs below 10° C., but food stored above this temperature may become dangerous fairly rapidly.

Diagnosis.

The symptoms of botulism in man are generally so characteristic as to render the disease capable of being diagnosed on clinical grounds. To confirm this diagnosis the following procedure should be adopted.

A. Demonstration of Botulinum Toxin in the Suspected Food.—For rapid diagnosis the food is suspended in saline, and injected intraperitoneally into three mice. A few hours before the injection, one mouse is given subcutaneously a small dose of antitoxin Type A and another Type B. Alternatively the food suspension may be added to the antitoxin, and the mixture injected subcutaneously. If the control mouse and one of the protected mice die, it may be provisionally concluded that *botulinum* toxin was present in the food, corresponding to the type of antitoxin which was given to the surviving mouse.

Meanwhile the food should be seeded into 2 per cent. glucose broth, Hitchens' medium (0·2 per cent. dextrose infusion broth containing 0·1 per cent. agar), beef heart peptic digest liver broth, peptonized bullock's heart broth (de Lavergne and Abel 1925), or cooked meat medium, and incubated anaerobically for 10 days at

35° C. The culture is then filtered, and the filtrate tested by intraperitoneal injection of mice or subcutaneous injection of guinea-pigs; antiserum Type A and B should be administered to two of the animals in order to determine the type of toxin present.

B. Isolation of the Bacillus from the Food.—Pure cultures may be obtained by heating broth cultures to 80° C. for half an hour to destroy contaminating non-sporing bacilli, and seeding into deep agar cultures, which are incubated anaerobically, preferably in the presence of added CO_2. The characteristic colonies should be picked off, grown in liquid medium, and tested for toxin production (Burke 1919*b*). Single colonies may likewise be obtained by plating the broth culture, after heating, on 5 per cent. horse blood extract agar plates incubated anaerobically (Wheeler and Humphreys 1924).

C. Demonstration of Botulinum Toxin in the Blood and Tissues.—Toxin may occasionally be demonstrated in the circulating blood during life. Schneider and Fisk (1939) report one successful instance in a case that later proved fatal, though they were unsuccessful in 3 non-fatal cases. The same authors succeeded in demonstrating the presence of toxin in the liver of 3 fatal cases at autopsy.

D. Isolation of Cl. botulinum from the Patient's Fœces or Vomit.—It is worth while attempting to culture the organism from the patient's fæces or vomit; the same method should be employed as for culturing it from food. Wheeler and Humphreys (1924) obtained pure cultures from the fæces of a woman on the 6th day of disease. Positive results have also been reported on fæces taken from the 6th to the 12th day of the disease (Dubovsky and Meyer 1922*a*).

E. Isolation of Cl. botulinum from the Intestinal Contents and Viscera at Autopsy.—*Cl. botulinum* does not usually invade the body, but it may occasionally be isolated from the liver (Dubovsky and Meyer 1922*a*) or spleen (Stricker and Geiger 1924).

F. Other Methods of Examination.—In patients that recover, antitoxin corresponding to the type of the organism concerned may sometimes be demonstrated in the serum. Thus Stricker and Geiger (1924) found antitoxin present in the serum of two patients on the 14th day after the consumption of the affected food; 0·25 ml. of the serum protected mice against 15,000 M.L.D. of Type A toxin, but not against Type B toxin.

Prophylaxis.

Sufficient information is now available about the conditions governing the destruction of *Cl. botulinum* in commercially canned foods to enable processing to be carried out satisfactorily. No outbreaks of botulism have, in fact, been caused since 1925 by foods preserved in American canning factories (Tanner, Beamer and Rickher 1940). Home-canning, on the other hand, is generally acknowledged to be fraught with danger, since the temperature attained in heating is as a rule too low to destroy the spores. Even fractional sterilization, which is possible in the home, is unreliable, because the spores may not develop in the meantime (Burke 1919*c*). In most outbreaks the food has been abnormal in appearance and odour. Bulging of the tin, the presence of gas bubbles on opening, a disintegrated appearance of the food, and a rancid smell, should be sufficient to condemn the food. On no account should such food be eaten, even after cooking (Tanner and Twohey 1926). But in some toxin-containing cans no evidence of spoiling is detectable (Schoenholz *et al.* 1923).

Prevention of botulism due to the consumption of made-up meat foods is particularly difficult. Van Ermengem (1897) lays emphasis on the necessity in pickling hams of using strong brine, which is unfavourable to the development of the organism.

In handling suspected food care should be taken not to allow it to come in contact with cuts; Geiger (1924) states that the toxin may be absorbed from broken skin areas, mucous surfaces, and fresh wounds.

Treatment.

The toxins produced by Types A and B of *Cl. botulinum* are antigenically distinct. Antitoxic sera can be prepared by the injection of rabbits (Nevin 1921), goats (Kempner 1897, Forssman 1905) and horses (Leuchs 1910) with each type of toxin. The antitoxin neutralizes the toxin according to the law of multiple proportions (Kempner 1897). Its therapeutic properties are limited. Injected before or simultaneously with the toxin it is protective for guinea-pigs and mice. Kempner (1897) found that 300,000 neutralizing doses, given 24 hours after the injection of the toxin, saved the life of a guinea-pig. Similar results were obtained by Kempner and Pollack (1897). Toxin-antitoxin mixtures given by the mouth are said to be dissociated in the stomach (Leuchs 1910). No international standard has yet been laid down for the antitoxin, but the intravenous inoculation of mice with toxin-antitoxin mixtures appears to be a promising method of titration (Glotowa and Dankerowitz 1935).

In the treatment of human cases antiserum has not yet been proved to be effective. Some favourable results have, however, been reported (McCasky 1919, Geiger 1920). Large doses, 50 ml. or more, of polyvalent serum, or of monotypical serum if the type of the intoxicating organism is known, should be given intravenously every day till the patient recovers, or all hope is abandoned. A prophylactic dose of 10 ml. should be given intramuscularly to all who have partaken of the poisonous food, and who have not yet developed symptoms of the disease. The antitoxin unit in the U.S.A. is that amount which prevents death within 4 days of guinea-pigs weighing 250 gm. injected with 1,000 M.L.D. of toxin.

Burke, Elder and Pischel (1921) state that liquid soap neutralizes the toxin, and that olive oil prevents its absorption from the gut. They advise therefore the use of high enemas of soap and olive oil. Iodine and potassium permanganate are both able to destroy the toxin *in vitro*, and might reasonably be given by the mouth. Alcohol precipitates the toxin (Armstrong *et al.* 1919); and it is possible that frequent small doses of brandy might prove beneficial. Mutch (1937) draws attention to the value of medicinal kaolin in the treatment of food poisoning on account of its ability to adsorb toxin. It is doubtful, however, whether any of these methods is likely to be of value in practice, since sufficient toxin will already have been absorbed by the time treatment is begun.

Botulism in Animals

Of recent years considerable attention has been devoted to a study of diseases of domestic animals characterized as a rule by fairly sudden onset, paralytic symptoms and often death. In many instances it has been possible to demonstrate a relationship between the type of fodder used and the occurrence of the outbreak. Organisms of the *botulinum* type have frequently been isolated from the animals and from the fodder, and the toxin produced in culture has been shown to be capable of reproduc-

ing the symptoms of the disease when given by the mouth or inoculated subcutaneously. The complete chain of evidence necessary to incriminate these organisms in the causation of the disease has often been lacking, but there seems to be little question that in many outbreaks the diagnosis of botulism has been essentially correct.

Great confusion exists about the exact identity of the various organisms isolated. Because some of them differ in their toxin production from the classical *Cl. botulinum* A or B types, the names *Cl. parabotulinum*, *Cl. parabotulinum bovis*, or *Cl. parabotulinum equi* have been suggested, and the disease caused by them has been termed parabotulism. This is not the place to discuss bacteriological nomenclature, but we are in entire agreement with Weinberg and Ginsbourg (1927) that for the moment these organisms should be regarded as varieties of *Cl. botulinum* and referred to as *Cl. botulinum* Type C, D, or E. Their relationship to each other and to the two classical types is very uncertain, and apart from slight differences in the nature of the toxin produced, there seems to be nothing that would justify their elevation to specific rank. Moreover, since some of the recorded outbreaks have been traced to toxin produced by the classical A or B types, and others in the same species of animal to toxin of the C, D, or E types, there seems to be no justification in referring to the former group as instances of botulism and to the latter as instances of parabotulism.

A complete study of the immunological behaviour of the toxins produced by these various organisms has not yet been made. The limited information available seems to show that the toxin of Types A and B is lethal, when given *per os*, to monkeys, ducks, horses, and laboratory animals, but probably not to goats. Type C_α is toxic by the mouth to ducks, slightly so to laboratory animals, but non-toxic to monkeys and goats. Type C_β is toxic by the mouth to monkeys, goats, ducks, and slightly so to laboratory animals. Type D is toxic by the mouth to goats, horses, and slightly so to laboratory animals, but not to monkeys. Type E is toxic by the mouth to horses. Both Types D and E seem to be very closely related to Type C (see Theiler *et al.* 1926–1927, Theiler 1928, Robinson 1929*a*, *b*, Gunnison and Meyer 1930, Gunnison and Coleman 1932).

Forage Poisoning in Horses.—Forage poisoning is a very common disease in America, affecting several thousand horses annually; numerous cases have been recorded in Europe and in Egypt. Buckley and Shippen in 1917 observed that experimentally induced botulism in horses closely simulated naturally occurring forage poisoning. From toxic oat-hay and ensilage they isolated a bacillus resembling *Cl. botulinum*; experimental intoxication with this organism could be prevented by the administration of anti-botulinum serum. Graham and Brueckner (1919) isolated an organism like *Cl. botulinum* from a corn ensilage that had been responsible for an outbreak of forage poisoning. Horses fed with 2 ml. of a broth culture of this organism manifested clinical symptoms of forage poisoning—difficulty in mastication, ptyalism, muscular weakness, pharyngeal paresis, recumbency, dyspnœa, protruding and pendulous tongue, mucous discharge from the nostrils, marasmus and enuresis—and died in a week. At necropsy lesions similar to some of the gross lesions occurring in forage poisoning were observed. Horses given a prophylactic dose of *botulinum* antiserum on the previous day recovered. On the other hand, Gaiger (1924) in this country has found that horses are comparatively insusceptible to *Cl. botulinum*, whether the culture is given by mouth or inoculated into the tissues. In view of the widespread distribution of *Cl. botulinum*, it is

obviously insufficient to demonstrate its presence in the fodder, or in the intestinal canal of the animal ; it must be shown that the contents of the intestine are definitely toxic.

In South Africa Theiler (1928) made some interesting observations on forage poisoning in mules. Circumstances surrounding the death of two mules in the same manger suggested that the food had become contaminated. Examination revealed the presence of a semi-decomposed rat in the hay, and bacteriological investigation left no doubt that the carcass of the animal contained *botulinum* toxin which had contaminated the hay. The part played by rats in the spread of botulism in horses and cattle is dealt with by Theiler and Robinson (1927) and Robinson (1929*a*). The organism isolated in South Africa is referred to as the E type, but it is closely related to the C_β type of America and Australia.

Forage poisoning is a wide term covering a number of different conditions, and it is not to be thought that it is uniformly due to poisoning with the toxin of *Cl. botulinum*. According to Walker (1929), the grass disease of this country is almost certainly different from botulism, while according to Gordon (1934) a disease in some respects resembling grass sickness may result from intoxication with products of *Cl. welchii* (see Chapter 36).

Botulism in Cattle and Sheep.—Forage poisoning in cattle is commonest between the ages of 6 months and 2 years ; the mortality is 2–10 per cent. (Graham and Schwarze 1921*b*). From a corn silage that was shown to have been responsible for an outbreak in cattle on two different occasions, Graham and Schwarze (1921*b*) isolated *Cl. botulinum* Type B. Whether the organism had any causal relationship to the poisoning was not definitely ascertained.

Dubovsky and Meyer (1922*a*) isolated *Cl. botulinum* from the liver and mesenteric glands of two cows suffering from ictero-hæmoglobinuria. In Australia Seddon (1922) has investigated an epizootic disease of cattle known by the names of Midland cattle disease, impaction paralysis, or dry bible ; this disease appears to be identical with the *lamziekte* of South Africa. From animals dying of the disease he isolated an organism, which he called *B. parabotulinus* ; this organism is now referred to as the C_β type of *Cl. botulinum*. Experimentally its toxin gave rise to bulbar paralysis in cattle.

Our knowledge of botulism in cattle has been extended by Theiler and his colleagues (1926–27) working on lamziekte in South Africa. This disease, which is characterized by paresis and paralysis, principally of the locomotor system, but sometimes of the muscles of mastication and deglutition, occurs in areas where the phosphorus content of the soil, and hence of the pasturage, is deficient. According to Theiler, the affected animals have a craving for phosphorus. This they endeavour to satisfy by eating the debris of carcasses, especially bones, which they find on the veld. Some of these carcasses, or the remains of muscle around the bones, happen to be infected with *Cl. botulinum*, and if sufficient toxin has been produced by the multiplication of this organism, the animals are liable to develop the characteristic symptoms of lamziekte (see also Seddon 1927). The disease can be prevented by feeding bone-meal to the animals ; this satisfies their craving for phosphorus, and so prevents their indulging in the so-called practice of " osteophagia." The infecting organism appears to be mainly of the D type, but, as already noted, it is closely related to the C_β type found in Australia by Seddon. According to Scheuber (1929), it is found in the soil near decomposing carcasses, and often in the intestinal contents of both sick and healthy animals.

Bennetts and Hall (1938) find that botulism of cattle and sheep in Western Australia results largely from the eating of carrion containing the toxin of Type C. Experimentally, they were able to show that as little as 3–5 gm. of toxic rabbit carrion might prove fatal to sheep. The length of time that carrion remains toxic varies with the rainfall and other factors, but sometimes it may be as long as six months. *Vaccination* with two doses of alum-precipitated *botulinum* toxoid at an interval of not less than two months conferred on both cattle and sheep a high degree of immunity.

Limberneck in Chickens and Duck Disease.—In 1918 Dickson made the following statement: " In the series of outbreaks (of botulism) which I have investigated it has been the rule to find that varying numbers of chickens have died from limberneck." This disease is characterized by weakness, muscular incoordination, a drooping neck, anorexia, prostration, and coma. Death frequently follows. Geiger, Dickson and Meyer, writing in 1922, were able to collect records in the U.S.A. of 103 outbreaks since 1910 with 3,500 deaths. Evidence that limberneck is an avian type of botulism is rapidly accumulating.

The toxin of *Cl. botulinum* has been demonstrated in the crop and intestinal contents of fowls dying of the disease (Graham and Schwarze 1921*a*, Graham and Boughton 1923*a*, Geiger *et al.* 1922). Experimentally it has been found that the feeding of toxic material gives rise to symptoms of limberneck (Dickson 1918). The disease has frequently followed the consumption of home-canned string beans (Meyer and Dubovsky 1922*b*). Most of the outbreaks investigated have been due to Type A, but there is evidence that Type B may be toxic to chickens (Geiger *et al.* 1922).

In 1920 Wilkins and Dutcher concluded from their experiments that limberneck was a disease resulting from paralysis following the ingestion of fly larvæ (*Lucilia cæsar*). Two years later Bengtson (1922*a*, 1923) isolated from the larvæ an organism similar in many respects to *Cl. botulinum*, which in large doses reproduced the symptoms of limberneck. This organism she called *Cl. botulinum* Type C (1923). These findings were confirmed by Graham and Boughton (1923*a*, *b*). It would appear therefore that chickens may develop limberneck from ingestion of fly larvæ containing *Cl. botulinum*; the evidence, however, is as yet insufficient to establish this conclusively.

A disease of **ducks** has been reported in different parts of the world (see Gunnison and Coleman 1932) which appears to be a form of botulism. Several large outbreaks have occurred in Canada and the United States. *Cl. botulinum* Type C has been isolated from the liver, and the corresponding toxin has been demonstrated in the bodies of ducks dying from this disease. Intoxication appears to be due to the consumption of food material in which the organisms have been multiplying, or to the ingestion of infected fly larvæ. Quortrup and Holt (1941) and Quortrup and Sudheimer (1943) have made some interesting observations on the ætiology of the disease. They find that *Cl. botulinum* Type C can grow well and produce toxin in decaying vegetation in the duck marshes. Growth is favoured by the presence of *Ps. pyocyanea*, which uses up oxygen and reduces acidity, and is hindered by certain other organisms which produce acid fermentation or destroy the toxin (see Sherman, Stark and Stark 1927). Whether an epidemic occurs among the ducks or not in any given year depends upon the balance in Nature between the favouring and the inhibiting factors.

Sporadic cases of botulism have been reported in a number of *other animals and birds* (see Robinson 1929*b*). Outbreaks of poisoning in cats, dogs, and goats have followed the consumption of home-canned string beans (Geiger *et al.* 1922). Experimentally, Graham and Eriksen (1922) found dogs to be resistant to feeding with *botulinum* toxin, but to be susceptible to Type A, not to Type B, toxin on subcutaneous injection.

CHAPTER 73

PLAGUE, PASTEURELLOSIS, AND PSEUDOTUBERCULOSIS

PLAGUE

Introductory

Plague has been one of the greatest scourges of the human race. From time to time it has swept over the world in relentless waves, exacting a toll of life probably unequalled by that of any other epidemic disease. In the 5th and 6th chapters of the 1st Book of Samuel there is an unmistakable account of bubonic plague. Before the Christian era 41 epidemics are on record; during the 1,500 years following the birth of Christ there are records of 109 epidemics, including the great plague of Justinian's reign, and the Black Death of the fourteenth century. Between 1500 and 1720 there were 45 pandemics of plague (Editorial 1925*a*). During the eighteenth and the nineteenth centuries it was comparatively quiescent, being confined almost entirely to endemic foci in various parts of Asia; but at the close of the last century it sprang once more into activity. Starting in Hong-Kong in 1894, it invaded India, Japan, Asiatic Turkey, and European Russia in 1896; the following year it reached Madagascar and Mauritius. In 1899 Arabia, Persia, the Straits Settlements, Austria, Portugal, British South Africa, Egypt, the French Ivory Coast, Portuguese Africa, the Argentine, Brazil, Paraguay, and the Hawaiian Islands were affected. There was a small outbreak at Glasgow in 1900, and in the same year the disease appeared at Sydney in Australia and at San Francisco, California. Undoubtedly the brunt of the disease was borne by India, where in the 20 years 1898–1918 more than 10 million deaths were recorded (White 1918–19).

At the present time plague is spread widely but unevenly throughout the world. One of the most disturbing features is the progressive infection of rodents that is occurring in America, South Africa, and apparently certain other countries; these animals form a reservoir for the conservation of the plague bacillus.

The causative organism was isolated independently and almost simultaneously by Kitasato (1894) and by Yersin (1894), at Hong-Kong in 1894. Numerous workers, particularly Ogata (1897), Simond (1898), and Gauthier and Raybaud (1902, 1903) were responsible for showing that the disease is primarily one of rodents, and that it is spread to man by the agency of infected fleas. This conception was criticized by several workers (Nuttall 1898, Galli-Valerio 1900, 1903), but was definitively proved to be correct by the English Plague Commission (Report 1906).

Epidemiology.

There are certain parts of the world from which plague never dies out; these constitute permanent endemic foci, and serve as starting-points for epidemics.

The maintenance of infection in these areas depends on the rodent population. In the South-Western Himalayas it is the rats that are infected, in the Kirghiz Steppes it is the spermophiles, in Transbaikalia the tarbagans, in California the ground squirrels, and in South Africa the gerbilles. Periodically epidemics of plague break out amongst these rodents, exterminating a large proportion of them. For some time infection lies dormant, manifesting itself only by isolated deaths. Then later, as the animals breed and a fresh susceptible population arises, another wave occurs, leading again to decimation of the herd (Elton 1925).

Man is infected from these animals either directly or, more often, by the intermediation of fleas. Year by year, single cases of plague, or groups, occur, small in themselves but sufficient to show that the disease is still smouldering. So long as these foci remain secluded they are of little importance; but once communication is set up with the surrounding country, there is a danger that plague may take on epidemic spread.

An epidemic starting in this way runs a characteristic course. In the pre-epidemic phase there are a few cases separated by considerable intervals of time. This is succeeded by the epidemic phase in which a rapid succession of cases occurs constituting the major portion of the outbreak. Finally there is a decline resembling the commencement, but not so long drawn out. Infection does not occur by direct contact with the sick; it spreads by contiguity from place to place, so that an increasing number of small foci are established. Often the infection seems to be localized to buildings, particularly grain stores, warehouses, or shops; in these, many cases of plague are contracted by people who have no immediate relation to each other. Plague has a predilection for dirty, insanitary dwellings, and more particularly for their ground floors; it attacks the lowest class of the population living under the worst conditions.

Infection may also occur *per saltum*. A focus of plague suddenly appears several miles—sometimes hundreds of miles—from the primary focus, and serves in its turn as the centre from which infection may spread to the surrounding localities. The contiguous mode of spread is dependent on the gradual dissemination of plague amongst the rats; *per saltum* infection results either from the transportation of rats or rat fleas by railways, ships, or other means of communication, or by human beings infested with rat fleas. It is probably due to importation of plague from cities that villages are infected. Greenwood (see Report 1911, p. 47) obtained evidence that villages situated near railways were more liable to plague than villages not so situated.

Though bubonic plague has occurred in nearly every part of the globe, it is confined chiefly to the warmer latitudes (Robertson 1923). Extreme heat and dryness of the atmosphere are inimical to its spread; thus in India it occurs during the colder months of the year, when the mean temperature is between 50° F. and 85° F., and the air has a high relative humidity, or, as it is sometimes expressed, a low saturation deficiency. According to White (1918–19), humidity is the most important factor in the spread of plague in India; the years of maximum mortality have been the years with a high mean relative humidity. This was particularly true of the Punjab and Northern India (White 1918–19).

The case mortality of bubonic plague is about 60–90 per cent., of pneumonic plague 100 per cent.

In Bombay the English Plague Commission (Report 1907, p. 724) determined

that prior to the annual outbreak of human plague there was an epidemic amongst the rats. First the rats belonging to the species *Rattus norvegicus* (*Mus decumanus*) were affected. After an interval of about 10 days an epizootic appeared in the rats of the species *Rattus rattus* (*Mus rattus*); and after a further interval of 10 days the human epidemic broke out. From this they inferred that *R. rattus* was infected from *R. norvegicus*, and subsequently conveyed the disease to man. It was further observed that plague persisted in *R. norvegicus* during the off-season—in Bombay from June to December—and flared up at the onset of the colder weather (Fig. 286, p. 1630).

The transference of plague from rat to rat and from rat to man occurs almost exclusively by fleas. Chief amongst these are *Xenopsylla cheopis* and *Ceratophyllus fasciatus*—the rat fleas. It has been shown that in the absence of their specific hosts, both of these types of flea will bite human beings. Plague is essentially a septicæmic disease; towards the end of an attack the bacilli are present in the blood in enormous numbers, and are readily imbibed by the fleas that infest the rat. When the animal dies, the fleas leave the corpse and wait for a suitable opportunity to attach themselves to a fresh host. Meanwhile the bacilli multiply in the proventriculus, often to such an extent as to block it completely, and prevent access of food to the stomach. A flea in this condition is hungry, and when it succeeds in finding a new host, attacks it with vigour. The act of sucking, however, only distends the already contaminated œsophagus, and on the cessation of the pumping act some of the blood is forced back into the wound (Bacot and Martin, see Report 1914). Sometimes a temporary passage is cleared through the mass of obstructing bacilli; this fails, however, to restore the lost valvular function to the proventriculus; it merely leaves a passage through which the blood can flow out of the stomach as freely as it enters. Hence after a full meal, blood extends from the posterior portion of the stomach to the anterior chamber of the pharyngeal pump. Such a flea is probably more dangerous than one whose proventriculus is completely blocked, since the contents of the stomach can be regurgitated into the wound with greater freedom (Report 1915*b*).

The length of time that a flea can remain *infected* depends on several factors, chief of which are temperature and humidity. In India fleas were found to harbour plague bacilli up to 47 days (Report 1915*a*), in Madagascar for several weeks (Girard 1936), and in the United States for as long as 130 days (Eskey and Haas 1940). Survival of the bacilli in the flea is favoured by a low temperature—about 50° F.—and a nearly saturated atmosphere; adverse factors are a temperature over 80° F., or an even lower temperature with a dry atmosphere (Liston 1924). But the time that fleas can remain *infective* is much shorter; most of them die in a day or two, and the limit of infectivity is probably about 7–14 days.

It has been suggested that the bacilli in the flea's stomach may be attacked by the phagocytes in the rat's blood which has been ingested; when the temperature rises the phagocytes become more active. This may explain why a flea clears itself more quickly at a high than at a low temperature, and also why, if it is fed on healthy blood after being infected, it clears itself more quickly than when it is starved. The clearance is said to be still more rapid when the flea is fed on the blood of immunized animals (Report 1908, p. 260). It is possible that in this manner the increasing proportion of immune rats towards the close of an epidemic exercises an inhibitory effect on the spread of the disease.

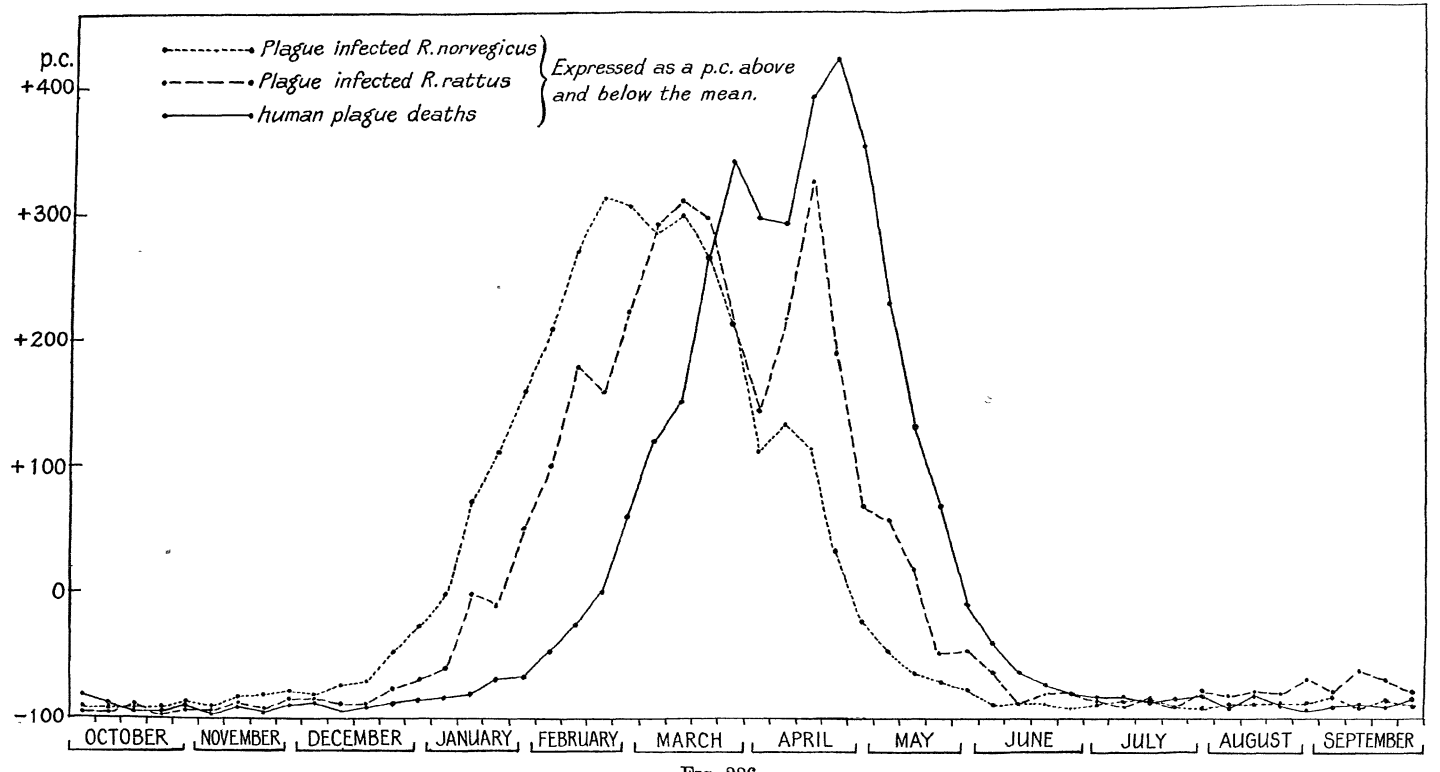

FIG. 286.

Chart illustrating the sequence of epidemic plague in rats and man. The figures are expressed as percentages above and below the mean. (After the English Plague Commission in India.)

Plague in Rats.

In India the two species mentioned above are chiefly responsible for the spread of plague. *Rattus norvegicus* is the large grey rat; it lives in sewers, stables, and garbage. *Rattus rattus* is the black rat; it is smaller and less fierce than the grey rat, and, living in houses or their immediate neighbourhood, it comes into closer contact with the human population. The natural mode of infection of rats appears to be almost entirely by fleas. It is possible that animals may acquire the disease by devouring their dead companions; but considering that it is not easy to infect rats by feeding on plague material, and that the post-mortem appearances in rats dying naturally of plague are different from those of rats experimentally infected by feeding, it is doubtful whether this is more than a rare occurrence.

In Bombay, of the dead rats examined during 1905–06, 22·2 per cent. of *R. norvegicus*, and 16·7 per cent. of *R. rattus* were infected with plague. Of the live rats the figures were 0·85 per cent. and 0·37 per cent. respectively. Thus plague was commoner in *R. norvegicus* than in *R. rattus* (Report 1907, p. 724). The susceptibility of the two species to experimental inoculation with plague was almost identical. In Sydney during $2\frac{3}{4}$ years ending December 31, 1904, 125,872 rats and mice were caught and examined; plague was identified in 0·37 per cent. (Thompson 1906).

During the height of the epizootic the lesions are those of acute plague, but during and subsequent to the decline, a number of healthy rats are encountered with atypical lesions. One of the commonest of these is a large abscess in the spleen or liver, containing plague bacilli. The rats, though infected, have evidently been able to withstand the attack. Swellengrebel and Hoesen (1915) in Java, and Bordas, Dubief and Tanon (1922) in France found a number of rats with atypical lesions containing plague bacilli of lowered virulence; on passage through one or two guinea-pigs they became fully virulent again. Williams and Kemmerer (1923) in New Orleans confirmed the existence of *latent plague* in rats. It has also been found among other rodents in Russia and the United States. Whether these animals act as chronic carriers of the disease and are responsible for keeping alive the infection from one epizootic to the next is still an open question. Most workers are disposed to attribute more weight in this respect to the survival of plague bacilli in the flea rather than in its host (Girard 1936, Eskey and Haas 1940).

Experimental Transmission of Plague in Rats.—It has been abundantly demonstrated by different workers that plague does not spread from rat to rat by contact in the absence of fleas. On the other hand infection spreads readily in the presence of fleas, even though the animals have no immediate contact with each other. Two experiments of the English Plague Commission will illustrate this.

EXPERIMENT 1.—(Report 1910.) Bombay rats were inoculated with plague and mixed with normal rats in godowns. In one set of godowns fleas were excluded, but in the other set they were permitted to multiply. In the flea-free godowns none of the normal rats, which were in continuous contact with the infected rats, developed plague, whereas in the others infection spread rapidly (Table 152).

The rats dying of plague in the flea godowns nearly all showed cervical buboes, indicating that the site of infection had been on the head or neck; this is the situation on which the fleas chiefly congregate.

EXPERIMENT 2.—(Report 1906, p. 421). This was a repetition of an experiment performed by Gauthier and Raybaud (1902, 1903). Two wire-mesh cages were employed,

TABLE 152

EFFECT OF FLEAS ON THE MORTALITY OF RATS IN EXPERIMENTAL EPIDEMICS.

Inoculated rats put in	84	70
„ „ died of plague	73 or 86·9%	63 or 90%
Normal rats put in	125	125
„ „ died of plague	0	57 or 45·6%
Plague rats eaten	3	1
Fleas present	None	About 24 per rat

each standing in a shallow tray filled with dry earth or sand. The cages were enclosed in a single glass box, the roof of which was covered with fine muslin impervious to fleas (see Fig. 287). Rats were introduced through the lids of the cages, and the lids themselves were covered with fine muslin. Into Cage X was placed a rat, inoculated with plague, together with 10 to 20 fleas. As soon as the rat was dead, a healthy rat was placed in Cage Y. The carcass of the first rat was allowed to remain in X for 8 to 12 hours after the animal's death. During that time fleas transferred themselves to the new rat through the wire mesh of the cages. Immediate contact between the two rats was absolutely prevented. This experiment was repeated several times, and in 69 per cent. of instances in which healthy, presumably non-immune, rats were used, the rat in Cage Y contracted plague.

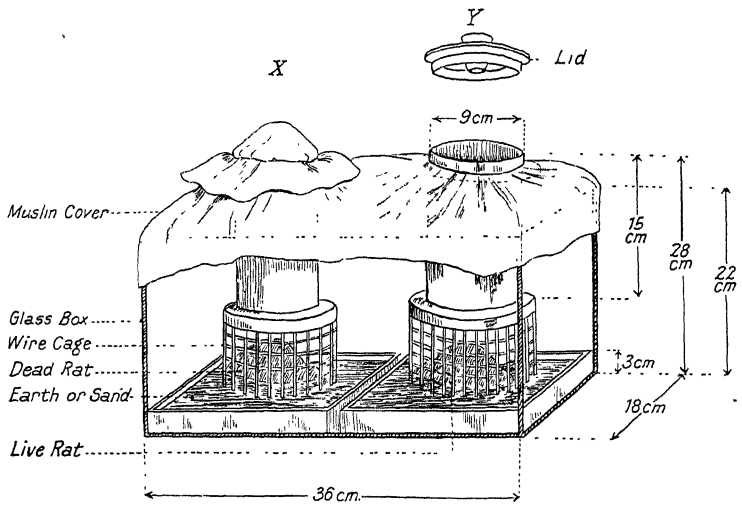

FIG. 287.

The wire-mesh employed was 3 mm.; in the figure it is shown much larger, for the sake of clearness.

Experiments were also carried out on guinea-pigs (Report 1906, p. 421). A series of 6 godowns were specially constructed by the Commission. The walls were of brick and mortar, 9 inches thick; the floors were of concrete on top of a high plinth. Each godown measured internally 7 ft. × 6 ft. Leading into the interior were double doors, lined with wire netting, between which was an inspection chamber. The essential difference in the structure of the godowns was in the roofs. Nos. 1 and 2 were roofed with country tiles, placed in four layers on the top of wooden laths. On the inside of this roof there

was a wire netting on a wooden framework in Godown 2, and two layers of wire netting, 10 inches apart, in No. 1. So that while rats could build their nests in the tiles of the roof, they were completely shut off from the interior of the godowns. Mangalore tiles were used for roofing Godowns 3 and 4; these do not afford so good a shelter for rats as country tiles; a single layer of wire netting separated the tiles from the interior. Godowns 5 and 6 were roofed with a single layer of corrugated iron fastened down with cement to the tops of the walls, so that no rats could nest at all. Godowns Nos. 1 and 3 had a small roof light; the rest were in darkness (Fig. 288).

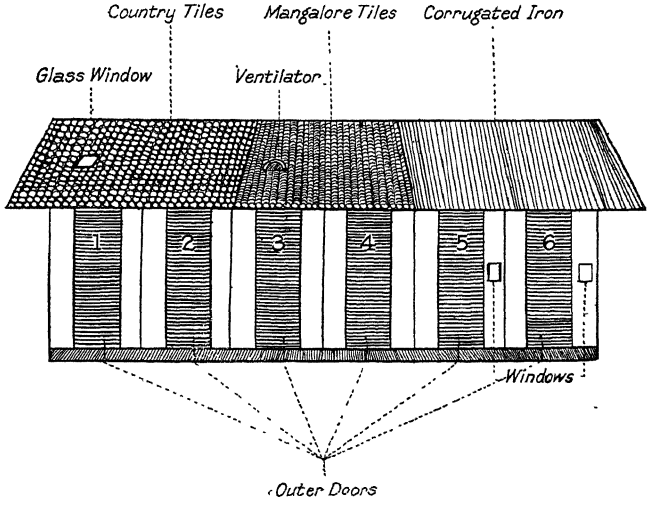

FIG. 288.

The doors opened into the left-hand side of each godown, not in the middle as indicated in the figure.

By allowing 3 guinea-pigs to run about in each godown for 6 days, and making flea counts every day, it was ascertained that the number of fleas varied in each instance with the accessibility of the roof to rats. Thus in No. 1, 54 fleas; in No. 2, 228; in No. 3, 40; and in No. 4, 70 fleas were caught in 6 days. In Nos. 5 and 6 fleas were few or absent. Incidentally this experiment brings out the importance of darkness in favouring infestation by fleas.

In these godowns a series of experimental epidemics was initiated amongst guinea-pigs, generally by introducing a number of animals experimentally infected with plague and adding normal animals to them. For the detailed results, reference must be made to the Commission's Report (1906); the conclusions that were drawn from them were as follows:

(1) Close contact of plague-infected with healthy animals, if fleas were excluded, did not lead to the production of an epizootic. Since the godowns were never cleaned out, close contact involved contact with fæces, urine, and discharges of infected animals, and the eating of contaminated food.

(2) Close contact of the young with the infected animals failed to infect the former; even the suckling of young animals by infected mothers proved ineffectual.

(3) If fleas were present, then an epizootic broke out, the rate of progress being in direct proportion to the number of fleas present.

(4) Infection can take place without any contact with contaminated soil. Thus, in one experiment, guinea-pigs placed in wire cages 2 inches above the ground developed plague. But when the cages were suspended 2 feet above the ground, none of them became ill, indicating that aerial infection does not occur.

In another experiment 2 monkeys were placed in Godown No. 2, in which 3 guinea-pigs had recently died of plague. Each monkey was in a separate cage of the same pattern, the only difference being that one was surrounded by a layer of tanglefoot (an adhesive substance) 6 inches wide, while the other one was unprotected. (A rat flea cannot jump farther than about 5 inches.) The roof of each cage was impervious to fleas, and the bottom was of teak wood, which prevented contact of the animal with the ground. After two nights in the godown the monkeys were removed and segregated. Two fleas were caught on the unprotected monkey, and five fleas were found stuck on the tanglefoot. The unprotected monkey soon became ill, developing a bubo in the right axilla, which contained plague bacilli. The protected monkey remained well.

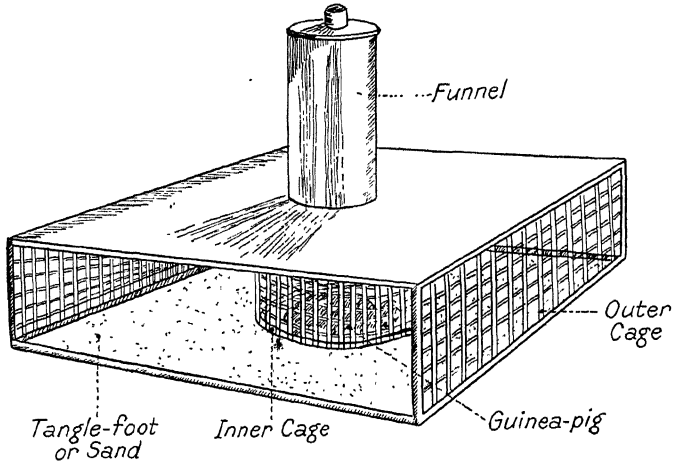

FIG. 289.

The outer large mesh wire netting, which has been omitted from one side of the outer cage, was to prevent the tanglefoot from being destroyed, and to prevent rats from coming into close contact with the guinea-pig. The tanglefoot prevented the access of fleas to the inner cage; the sand did not.

Equally suggestive were the experiments in the plague houses of Bombay. Guinea-pigs were allowed to run about in these houses to act as traps for fleas; the usual number of fleas—mostly rat fleas—caught in this way was about 20 per room. In 29 per cent. of instances guinea-pigs left in these rooms for from 18 to 40 hours contracted plague. The situation of the bubo was usually in the cervical region—explicable by the habit that fleas have of collecting round the under surface of the neck.

In other experiments guinea-pigs were placed in cages, of the pattern shown in Fig. 289. One of the cages was surrounded by a 6-inch boundary of tanglefoot; the other by a layer of sand. When left in plague-infected houses, 24 per cent. of the animals in the unprotected cages developed plague whereas not one of the animals in the protected cages did so.

Mode of Spread of Plague in Bombay.—The conclusions drawn from these experiments receive support from epidemiological observations in the field. Plague in man predominates amongst the lowest classes, particularly those in dirty and

insanitary dwellings, where rats and fleas are numerous. The higher classes, such as the Parsees and the Europeans, suffer very slightly. The presence of an initial bubo renders it highly probable that infection occurs by the skin, and the predominant selection of the inguinal region for the development of the bubo suggests that the bacilli gain entrance through the skin of the leg In confirmation of this it has been noted by several observers that in about 5 per cent. of cases the first sign of plague is a small vesicle, surrounded by an area of redness (Simond 1898). This is found generally on the leg, and is undoubtedly due to the bite of a flea. Living plague bacilli are said to be uniformly present in these vesicles.

Though rats in Bombay breed throughout the year, both *R. rattus* and *R. norvegicus* breed most freely from June to October. The largest proportion of young rats in relation to the total population is reached in November and December.

Rat fleas are most prevalent during the months of February, March, April, and May. The infestation of *R. norvegicus* is more than double that of *R. rattus*. Thus the number of fleas per rat during these months is about 5 for *R. rattus* and 12 for *R. norvegicus*. In this connection it will be remembered that plague is commoner in *R. norvegicus* than in *R. rattus*. The epidemic season for rats and man lasts from January or February till April or May, the maximum prevalence being either in March or April. The sequence of events would appear to be as follows. During the hot season the rats breed freely, and a large susceptible population is produced. As the colder weather arrives, the fleas increase in numbers, and plague breaks out in *R. norvegicus*. This is rapidly followed by an epizootic in *R. rattus*, and this in its turn by the human epidemic. At the onset of the hot weather in May or June the flea population decreases rapidly, and plague in rats and man comes to an end for the year. The subsidence of the epidemic is accounted for partly by the increasing proportion of immune rats, and partly by the decrease in the number of fleas. With regard to the former it was found by the English Commission that Bombay rats captured towards the end of the epizootic were more resistant to experimental inoculation with *Past. pestis* than those at the beginning. Whether the rats that had survived the epizootic were more resistant *ab initio*, or had acquired immunity during the progress of the epizootic, it was impossible to say.

During the off-season sporadic plague occurs in rats, particularly *R. norvegicus*, and in man; but the conditions are obviously unsuitable for its spread on any but a small scale.

We have dealt at some length with the conditions prevailing in Bombay, because they have been investigated so thoroughly. In other parts of India much the same sequence of events has been observed, with, however, variations dependent on climatic and other factors. It is curious that 75 per cent. of the plague cases in India are distributed over the Punjab, the Bombay Presidency, and the United Provinces, when it is remembered that these areas contain less than a third of the total human population (Low 1920). This anomaly is explicable largely by the favourable climatic conditions existing in these areas for multiplication of fleas. Where these conditions are unsuitable, plague either does not occur or runs a diminutive course. Madras, for example, though bordering on the highly infected Bombay Presidency, is relatively free from plague. The probable reason for this difference is that the predominating rat flea in the Madras Presidency is

X. astia, which as Liston (1924) and Hirst (1926, 1927) have shown, is considerably less effective in carrying plague from rat to rat than *X. cheopis*. A supplementary, but probably less important, reason is that during about 7 months of the year the climatic conditions in certain parts of Madras are unfavourable both to flea reproduction and to the transmission of infection by rat fleas. It is noteworthy that in Madras and Colombo plague seems to be confined to areas in which *X. cheopis* is prevalent. While *X. astia* is indigenous to Southern India, *X. cheopis* has only been recently introduced—mainly by the grain and cotton trade. It is still spreading, or attempting to spread, in these new areas, and the incidence and severity of plague epidemics appear to be associated directly with the number of *cheopis* present (King and Pandit 1931).

The conclusions advanced by the English Commission (Report 1908, p. 266) on the seasonal prevalence of plague in Bombay and the Punjab were as follows: The *rise* of the rat epizootic, and therefore of the human epidemic, depends on (1) a suitable mean temperature, somewhat below 85° F. and in general over 50° F.; (2) a sufficient number of susceptible rats; (3) a sufficient number of rat fleas.

The *fall* of the rat epizootic and of the human epidemic depends on (1) a high mean temperature, 85° F. or over; (2) a diminution in the total number of rats and an increase in the proportion of immune to susceptible animals; (3) a diminution in the number of rat fleas.

In Egypt, Petrie and Todd (1924) were able to determine the influence of season on the spread of the disease. In the Southern Provinces the maximum incidence was in February or March; in Northern Egypt, at Alexandria and Port Said, it was in July. The optimum temperature for epidemic spread was 68°–77° F., and the optimum vapour pressure deficiency 1–10 millibars. These, too, were the optimum conditions for the development of fleas. There was a lag period of 4 to 6 weeks between the onset of favourable atmospheric conditions and epidemic prevalence of the disease in man; this was apparently taken up by the development and multiplication of *X. cheopis*. The two rodents chiefly concerned in the spread of plague were *Rattus rattus* and the Cairo spiny mouse (*Acomys cahirinus*). *X. cheopis* constituted from 90–100 per cent. of the fleas on these animals trapped in houses.

In the mountainous districts of Java, according to Otten (1932) fleas reach their maximum in October and November, and human plague reaches its maximum in December. The flea index follows the rise and fall of the saturation deficiency—just the opposite to what occurs in India.

It will be gathered that the conditions determining the epidemic spread of plague are very stringent. The links in the rat-flea-man chain must be delicately adjusted; a slight fault in one link is sufficient to impair the efficiency of the whole chain, or even to break it altogether. This is doubtless the reason why in countries where the conditions are not so favourable as in India, plague often has great difficulty in spreading (Robertson 1923). Several times during the present century it has been introduced into England, chiefly at the ports, yet it has uniformly failed to take hold. In East Suffolk, it is true, it is endemic in the rats (Bulstrode 1910–11, Eastwood and Griffith 1914, Macalister and Brooks 1914), having been imported probably in grain; but apart from attacking one or two persons it has shown no potentialities for spreading to the human population (see Greenwood 1935).

Plague in other Rodents.

GROUND SQUIRRELS AND OTHER AMERICAN RODENTS.—Plague first appeared at San Francisco in 1900. By 1904 it had spread from the rats to the ground squirrels—*Citellus beecheyi*—and had begun to pass eastward from the coast (McCoy 1910). In 1934 it was found that plague had crossed not only the central valleys of California, but also the Sierra Nevada mountains into the Great Basin section of Oregon. A new species of ground squirrel, *Citellus oregonus*, was shown to be infected. As a result of special field surveys it was learnt that by 1940 no fewer than ten States had been invaded. Three groups of rodents appear to constitute the main primary reservoirs of infection in the west: (1) ground squirrels in the coastal regions and northern part of the inter-mountain plateau; (2) wood rats in the southern deserts; and (3) white-tailed prairie dogs in the plateau regions of Arizona and New Mexico. A more limited reservoir is furnished by chipmunks, mantled ground squirrels, and marmots. Numerous species of fleas, lice, and ticks are concerned in the transfer of infection among these rodents (Eskey and Haas 1940).

Cases of human plague have been traced to contact with ground squirrels, but they have been few. During the ten years, 1930–39, only 8 cases were reported (Hampton 1940). If, however, plague should cross the Rocky Mountains and infect the urban rats of the middle west, a more serious situation might arise. (For a description of the progress in combating what is sometimes referred to as "sylvatic plague" in the western part of the United States the reader is referred to a series of articles by Meyer [1936, 1937, 1938, 1939].)

GERBILLES AND MULTIMAMMATE MICE.—Plague was introduced into South Africa in 1900–02 by rats in forage vessels coming from South American ports. Since then isolated outbreaks have occurred in different parts of the country without any explanation being apparent of the mode of infection. In 1921, however, a case of plague on a farm was traced to infected rodents. It was discovered that the gerbilles or Nachtmuis (*Gerbillus tateronia*) and the multimammate mice (*Rattus coucha*) in the locality were infected with plague (Mitchell 1921). Both of these animals come into fairly close contact with man. Plague spread rapidly in the rodents during 1923–24, and in that year there were 167 outbreaks of human plague in the Union, with 372 cases and 235 deaths. Large epizootics have occurred, killing off 80–90 per cent. of the veld rodents and 30–40 per cent. of the associated small carnivora—mongoose and suricat. The rodents are not completely exterminated by the disease; the survivors breed freely, so that in time another large susceptible population appears, which is likewise decimated by plague (Kauntze 1926). It is estimated that plague is distributed over about 50,000 square miles (Editorial 1925*b*).

SPERMOPHILES AND FIELD MICE.—Endemic plague in the Steppes of South-west Russia has been traced to spermophiles—*Spermophilus musicus* and *Sp. rufescens*—and to field mice. In winter when the spermophiles are hibernating, cases of human plague appear to be due to infection from wandering field mice, which take refuge in the thatched roofs of the houses (Zabolotny 1923). A number of cases in winter, however, appear to be of the pneumonic type (Radcliffe 1879–80). In certain provinces, such as Saratow, Astrakhan, and the Don province, marmots are also infected (Tschurilina 1930).

TARBAGANS.—Numerous outbreaks of plague have occurred in Transbaikalia, Mongolia, and Manchuria. The origin of these has been traced to infected tar-

bagans (Zabolotny 1923, Petrie 1924, Wu Lien Teh 1924). The tarbagan (*Arctomys bobac*) is a small rodent living in deep burrows. From September to April it hibernates, and the breeding season is in July and August. During April, May, June and September its skin is largely sought after by Russian and Chinese hunters for the manufacture of imitation sable. The tarbagan harbours fleas—*Ceratophyllus silantievi* Wagner—which will bite man when starved (Wu Lien Teh 1913). In its burrows there are certain passages used for the deposition of excrement, and the corpses of animals that have died during hibernation, as well as skin, bones, and other refuse. These passages are in absolute darkness, and are cool, moist, and of equable temperature; it is probable that they afford suitable conditions for conservation of the plague bacillus during the winter (Jettmar 1923).

During the summer, sporadic cases of bubonic plague occur amongst the tarbagan hunters. In the winter pneumonic plague occurs in epidemic form.

Pneumonic Plague.

The epidemiology of pneumonic plague is different from that of the bubonic form, one of the chief differences being that the former is highly contagious, whereas the latter is not.

Provided the conditions are favourable, primary pneumonic plague may spread with great rapidity. In 1910–11 the outbreak in Manchuria and North China levied a toll of 60,000 lives; in 1917–18 there were 16,000 deaths in South Mongolia and China, and in 1920–21 there were 9,000 deaths in Transbaikalia (Wu Lien Teh 1922). The epidemic is independent of rodents; it spreads directly by droplet infection from one person to another. The closer the contact, the more likely is infection to spread; this accounts for the prevalence of pneumonic plague in the winter, when overcrowding in insanitary dwellings is so common. This form of the disease appears to be uniformly fatal (Jettmar 1923).

In some countries, such as Manchuria, Transbaikalia, and the Kirghiz Steppes, bubonic plague occurs during the warm weather, and pneumonic plague during the winter. Under these conditions it seems probable that the outbreaks of pneumonic plague arise from cases of bubonic plague complicated by secondary pneumonia.

Bacteriology and Diagnosis of Plague in Man and Animals

Diagnosis of Natural Rat Plague.

During an epizootic the diagnosis of plague in rats can be made almost as well macroscopically as by microscopical examination. The signs and their frequency in *R. rattus* and *R. norvegicus* combined were as follows (Report 1907):

	Per cent.
(1) Subcutaneous congestion, particularly in submaxillary region	30·5
(2) Subcutaneous hæmorrhages, particularly in submaxillary region or flank	40·5
(3) Cervical œdema	10·0
(4) Single bubo	73·05
(*a*) Cervical bubo — 75 per cent. of cases of single bubo	
(*b*) Axillary bubo — 15·1 „ „ „ „ „	
(*c*) Groin bubo — 6·1 „ „ „ „ „	
(*d*) Sublumbar bubo — 3·8 „ „ „ „ „	

	Per cent.
(5) Multiple buboes	11·67
(6) Granular liver	55·5
(7) Pleural effusion	64·5
(8) Hæmorrhages in lungs and pleuræ	24·0
(9) Hæmorrhages in kidneys and suprarenals	8·5
(10) Granular spleen	4·5

Without doubt the presence of a bubo is the most important single indication of plague. In the early stage the gland is enlarged, congested, and shows hæmorrhagic points on section. When fully developed, it contains an area of grey necrosis confined to the medulla, or occupying the whole gland. The bubo is hard, and can be moved about under the skin with ease. Microscopically, plague bacilli are found in about 99 per cent. of buboes; in over half the buboes involution forms are present. The bacilli are best demonstrated by staining with carbol-thionin; with this dye they are faintly coloured except at the poles, which stain deeply.

The liver frequently shows a patchy distribution of alternate red and yellow areas—best described as mottling. In many instances there are small, grey or whitish areas of necrosis, giving the organ a stippled appearance as if it had been dusted with grey pepper; as a rule they do not project above the surface. The spleen is sometimes enlarged, and is firm and moulded over the stomach; sometimes it contains granules or actual nodules, which may be discrete or confluent. Occasionally a wedge-shaped portion of the spleen is converted into a cheese-like mass. Pleural effusion is a very characteristic feature; it is clear, abundant, and straw-coloured, less often blood-stained. The five most important signs of plague are: (1) bubo; (2) subcutaneous and general congestion; (3) granular liver; (4) congested spleen; (5) pleural effusion. Of these 1, 3, and 5 may persist in rats that have undergone putrefaction, and are then of great diagnostic value.

Microscopically, bacilli are most abundant in the bubo, then in the spleen, and least numerous in the heart's blood. Particular attention should be paid to the polar-stained barrel forms in fresh material, and to the characteristic rings and discs in putrefying material (Kister 1930). Cultures should be made from these three situations, single colonies picked off, and carefully studied.

Inoculation of guinea-pigs or mice should be made subcutaneously with a suspension of the bubo or spleen. If the animal has undergone putrefaction, and other organisms are likely to interfere with the inoculation test, pieces of the tissue should be rubbed on to the shaven abdomen of a guinea-pig. *Past. pestis* is able to penetrate the unbroken skin, whereas very few other organisms can do so. The Commission found that this test failed in only 2 per cent. of fresh and 10 per cent. of putrid rats.

In putrid animals the *thermoprecipitin test* is sometimes of value (Kraus 1897*b*, Piras 1913, Warner 1914, Philip and Hirst 1917). One part of the finely divided organ is mixed with 5 to 10 parts of distilled water, boiled for 5 minutes, filtered repeatedly through paper or asbestos wool under pressure till clear, and run on to the top of a specific serum in a small tube. In a positive reaction a precipitate appears in 5 minutes at 37° C., increasing to a maximum after 2 hours.

There are several other diseases that may be confused with plague.

Pasteurellosis in rats does not appear to be very common, but when it does occur it is most confusing (Smillie 1920, Wayson 1925; see also Mitchell 1930).

The bacilli are smaller, more regular, and differ from plague chiefly in their sugar reactions and in their formation of indole.

Past. pseudotuberculosis (rodentium) gives rise to an infection in rats often accompanied by the formation of nodules in the spleen and liver. As a rule these nodules are larger than those of plague, and stand out more from the surface. One means of differentiation is the injection of the organisms into white rats; these animals are said to be susceptible to plague but relatively resistant to pseudotuberculosis. *Past. pseudotuberculosis*, if examined in broth cultures after about 16 hours' incubation at 22° C., is generally found to be motile, whereas *Past. pestis* is uniformly non-motile. (For further differences between these organisms see Chapter 32.)

According to Levinthal (1931), buboes in both rats and guinea-pigs may be caused by *Bact. coli*. Differentiation is readily accomplished by growth on MacConkey agar. Agglutination of the organisms with an anti-plague horse serum is not always reliable, because the serum may contain agglutinins to *Bact. coli*.

Infection of rats with *Trypanosoma lewisii* may readily be confused with plague (Macalister and Brooks 1914). Diagnosis is easy on microscopical examination, since trypanosomes are found in large numbers in the blood.

The lesions of plague in other rodents are similar to those in rats, and need not be described separately. In ground squirrels there is a disease called Tularæmia, which closely resembles plague; cultivation is necessary to distinguish between them.

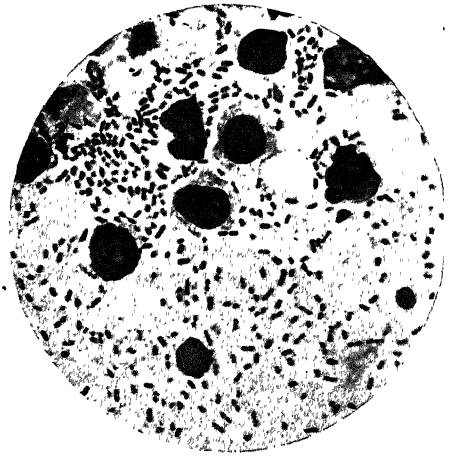

FIG. 290.—*Pasteurella pestis*.
Film from inguinal bubo of infected guinea-pig, showing the bipolar-stained ovoid bacilli (× 1000).

The diagnosis of epidemic plague in rats is comparatively simple, but great difficulties are met with in the sporadic form. The lesions are often atypical (Eastwood and Griffith 1914), buboes may be absent, and sometimes nothing characteristic may be noticed. Williams and Kemmerer (1923), in an examination of rats at Galveston, Texas, found 9 plague-infected rats, none of which showed any macroscopic signs of plague. The infection was discovered by gross or combined inoculations of the tissues of all rats in each day's catch. They advise that the rats should be divided into batches of ten, and the combined spleens or glands of each batch should be emulsified and injected into a guinea-pig. Even this method is not infallible, because at the decline of an epizootic or during an inter-epizootic period the virulence of the bacilli may be so low that the guinea-pig either does not die or dies with atypical lesions; in this case a fresh inoculation should be made from the guinea-pig, and repeated in series till the virulence of the organism is sufficiently exalted to give rise to typical plague. In the search for plague infection among ground squirrels and other similar rodents it has been found more satis-

factory to collect the fleas from the animals and inoculate them in pooled batches into guinea-pigs (Eskey and Haas 1940).

When a hitherto uninfected locality is invaded by plague, the rats may succumb rapidly to a septicæmic form of the disease, in which buboes are insignificant or absent (Philip and Hirst 1917). Such rats may appear almost normal to the naked eye, though the bacilli are seen microscopically in large numbers in the blood and viscera.

Towards the end of an epizootic, lesions of chronic or resolving plague may be found. The chief of these are: (1) chronic buboes; (2) necrotic areas in the spleen; (3) chronic abscesses in spleen, and more rarely in liver; (4) perisplenitis; (5) scars in spleen; (6) bisected or trisected spleen; (7) adhesions of spleen to surrounding structures. In these lesions bacilli may or may not be found.

Diagnosis of Plague in Man.

During Life.—A small vesicle is sometimes present on the leg in the early stages of the disease corresponding to the flea-bite. Microscopical examination of the fluid will show the presence of plague bacilli. The bubo, which is generally in the inguinal region, should be aspirated, and the fluid examined microscopically, by culture, and by animal inoculation (Fig. 290).

Plague bacilli are frequently present in the patient's blood, where they may be demonstrated microscopically or, preferably, by culture. In the early stages of the disease 34 to 60 per cent. of blood cultures have been reported positive by different observers; but Bonebakker (1936), making use of Kirschner's (1934) observation that pure bile constitutes an excellent medium for the growth of plague bacilli in blood, was able to demonstrate their presence in 85 per cent. The degree of bacteræmia is said to fluctuate considerably during the course of the disease (Report 1908, p. 221).

The German Plague Commission (Report 1899) found that the patient's serum often agglutinated the plague bacillus, though usually to a low titre 1/2 to 1/40. A positive test is of value, a negative one meaningless. In mild or chronic cases, when the diagnosis is in doubt, and the bubo is small, hard, and difficult to aspirate, the bubo should be excised and injected into a guinea-pig (Uriarte 1925). In pneumonic plague large numbers of bacilli are found in the sputum.

The fæces of plague patients do not contain *Past. pestis*; the urine often does (Ogata 1897)—in 19 to 30 per cent. of patients (Report 1908, p. 221).

After Death.—Microscopical, cultural, and animal inoculation tests should be relied on for diagnosis, the best material being the bubo or the spleen. If the cadaver is comparatively fresh, the tissue suspension should be injected subcutaneously or intraperitoneally into a guinea-pig; the latter method is more reliable if the organisms are few. In putrid cadavers the organ should be rubbed on to the shaven abdomen of a guinea-pig or on to its nasal mucosa (Zlatogoroff 1904, Girard 1934); the thermoprecipitin test may likewise be used. In frozen cadavers *Past. pestis* can be cultivated from buboes up to 102 days (Zlatogoroff 1904).

Immunity.

There is evidence that after plague has been epidemic among rats for a time it decreases in incidence and ultimately dies out. This process is associated with an increase in the immunity of the rats. It has been shown that rats from a plague-infected area are more resistant to experimental inoculation than those

from non-infected areas; and the young of resistant animals are said to enjoy a high degree of natural immunity (Liston 1924).

Sokhey and Chitre (1937), for example, in India collected 80 rats from each of a number of towns that had suffered in varying degrees from plague during the period 1899–1929, inoculated each of them with a standard dose of virulent plague bacilli, and observed the resulting mortality. They found that, in general, the proportion of animals dying was inversely proportional to the total human plague incidence in the town from which they were derived. Thus, in Bombay city, where plague had been prevalent, only 7·9 per cent. of the rats died; in Madras city, on the other hand, where there had been practically no plague, 91·1 per cent. died.

How far resistance is due to an increased genetic immunity in the strict sense, resulting from the operation of natural selection, and how far it is due to the acquirement of active immunity by the young animals as the result of latent infection, occurring perhaps at a time when antibody derived from the placental circulation or the colostrum is still present in the animal's tissues, it is difficult to say, but readers who are interested in this fascinating problem will do well to consult the review of the subject by Hill (1934). On the whole, the evidence points more to the importance of genetic immunity. For example, in Bombay city, over 2,000 rats were caught each night and examined at the Haffkine Institute. During two years not a single plague-infected rat was found (Sokhey and Chitre 1937). Again, in the region of Paris, where plague was introduced by infected rats in 1917, the resulting epizootic gradually declined after about 1920, so that by 1936 not a single rat out of 3,525 examined was found to be infected (Joltrain 1936). In view of these findings it is difficult to ascribe the increasing immunity of the rats to the persistence of a benign epizootic. It seems more probable that a strain of rats is evolved having a greater degree of natural resistance to plague infection than that to which the bulk of the original susceptible animals belonged.

Prophylaxis, Vaccination, and Serotherapy

Prophylaxis.—The aim of prophylaxis is to weaken or break the rat-flea-man chain by striking at one of its links. The rat constitutes the first link. Complete destruction of all rats and mice is, however, quite impracticable. The animals breed at such a rate as to render futile all attempts at extermination. According to the English Plague Commission the progeny of a single pair might number 858 in 16 months (Report 1911). Thompson in Sydney found that, in spite of an intensive campaign against rats and mice, the number caught each week was nearly uniform; there was no evidence that the slaughter policy was making any real impression on the general horde. Again, complete destruction of rats on ships is impracticable; if performed thoroughly it would cause more dislocation of the traffic than would be tolerated. It has been suggested by Rodier (1926) that a more efficacious method would be to kill all female rats caught, and liberate the males; the resulting polyandry, he considers, would lead to practical extinction of the species.

Rats are comparatively harmless so long as they do not come into intimate contact with human beings. The most hopeful policy is to render all houses, granaries, shops, and such places unsuitable as rat habitations. That this can be done successfully has been demonstrated in Java, where between 1914 and 1939 over 1,500,000 houses were remodelled (van Loghem 1939).

The second link in the chain—the flea—must be dealt with by strict personal

hygiene and domestic cleanliness. In the absence of dirt and litter the fleas have nowhere to breed. The possibility that other insects—bugs, flies, ticks—may share in spreading the disease has been carefully considered (Nuttall 1897, 1898, Report 1915*c*). There seems little doubt that lice and ticks play a part in the transmission of sylvatic plague (Hampton 1940), but their rôle in the spread of plague among rats would appear to be negligible.

Man forms the third link. Four measures are usually advocated: (1) Notification of cases or, in countries where this is difficult, registration of deaths. The diagnosis can be confirmed post mortem by splenic puncture. (2) Isolation of cases, which, except in pneumonic plague, is of little value, since man plays but a small part in the spread of the disease. (3) Evacuation, which is sound in theory, since it removes the susceptible population from the infected localities, but is very difficult in practice—at any rate on a large scale. (4) Vaccination, the chief value of which is, or should be, to protect an exposed population while effective preventive measures, such as the remodelling of houses to exclude rats, are carried out.

Against pneumonic plague we are as powerless as against influenza or other rapidly spreading respiratory disease; the most important measures are the isolation of the patients and the prevention of overcrowding, especially at night.

Vaccines.—Animals were successfully vaccinated against plague by several of the early workers (Yersin *et al.* 1895, Report 1899, Report 1910, p. 536). Different species appear to vary in their response to a given vaccine. According to Schütze (1939*a*) a high content of envelope antigen is required in the vaccine if rats and guinea-pigs are to be protected, but in the mouse this antigen is of less importance. These observations may explain some of the discrepancies between the protagonists of dead and of living vaccines. Sokhey (Report 1936, 1937), for example, using mice has apparently obtained very good results in the laboratory by the use of a killed vaccine made from a broth culture grown at 27° C., which is known to contain very little envelope antigen; whereas Otten (1936, 1938) using guinea-pigs and rats, and Pirie and Grasset (1938) using rats, found a dead vaccine to be greatly inferior in its protective power to a living vaccine made from a strain of modified virulence.

In the prophylaxis of human plague a killed vaccine has been extensively used in India, but of late years the successful use of living vaccines in Java and Madagascar has seriously challenged the older method.

Dead Vaccine.—Haffkine's vaccine is prepared from a 4-weeks' culture of *Past. pestis* at 27° C. in goat digest broth, killed by heat for 15 minutes at 55° C., and preserved with 0·5 per cent. phenol. According to Schütze (1934), it is desirable to neutralize the alkali in the culture before heating in order not to destroy the small amount of envelope antigen in the bacilli. The vaccine is standardized by a mouse protection test (see Taylor 1933, Sokhey and Maurice 1935, Sokhey 1939). Four ml. is the usual dose for an adult, given at a single inoculation. The protective value of this vaccine is difficult to assess. Most of the trials have been made in India, where exact collection of statistics is notoriously difficult. The selection of the groups for vaccination has in some instances not been above criticism. To give an adequate summary of the results obtained would require more space than can here be spared; the reader who wishes to examine the evidence is referred to the Indian Plague Commission's Report (1901). A summary, however, of the more important groups of figures is reproduced (Table 153).

TABLE 153

HAFFKINE'S VACCINE. INCIDENCE AND MORTALITY OF PLAGUE IN INOCULATED AND UNINOCULATED PERSONS IN 14 OUTBREAKS. (Modified from Taylor 1933.)

Average Population at Risk.		Inoculated.		Uninoculated.	
Inoculated.	Uninoculated.	Attacks.	Deaths.	Attacks.	Deaths.
123,134	168,638	803	385	4,014	3,194
Attack rate per 10,000 . .		65		238	
Death rate per 10,000 . . .		31		189	
Case mortality		48 per cent.		80 per cent.	

These figures suggest that inoculation confers roughly a fourfold protection against attack, and a sixfold protection against death. The effect of the vaccine probably lasts for some months.

Living Vaccines.—Otten, in Java, has been the chief advocate of the living vaccine. Having convinced himself (see Otten 1933, 1936) that no dead vaccine could protect guinea-pigs or wild rats satisfactorily, he turned to a living vaccine made from a strain of modified virulence that had been originally cultivated from a plague rat at Tjiwidej. A single dose of this vaccine was found to protect 80 per cent. of rats and over 90 per cent. of guinea-pigs against inoculation with a dose of virulent plague bacilli that killed 99–100 per cent. of the control animals. For human beings the vaccine is prepared by washing off with saline a 2–3 day agar culture grown at 30° C. It can be kept for a month in the ice-chest without loss of potency. At first it was used in two sub-districts of Java, when alternate persons only were inoculated. The results of this controlled trial, in which observations were made over a period of 5 months after vaccination, are summarized in Table 154.

TABLE 154

OTTEN'S VACCINE. MORTALITY FROM PLAGUE IN INOCULATED AND UNINOCULATED PERSONS (Otten 1936).

Sub-district in Java.	Inoculated.			Uninoculated.		
	Number.	Deaths.	Mortality per 1,000.	Number.	Deaths.	Mortality per 1,000.
Bandjaran . . .	18,479	28	1·5	20,669	103	4·9
Batoedjajar . . .	18,956	10	0·5	24,088	110	4·6
Total	37,435	38	1·01	44,757	213	4·75

There were larger numbers of young children in the control than in the vaccinated group; since there is evidence that susceptibility to plague is less in the first six years or so of life than later, the odds were probably weighted somewhat against the vaccinated subjects. Even so the mortality per 1,000 was 4 to 5 times higher in the control group.

Later figures given by Otten (1941) show the fall in the number of deaths in the residency of Priangan. Vaccination of 94 per cent. of the population of two

TABLE 155

PLAGUE DEATHS IN THE RESIDENCY OF PRIANGAN.

1934.	1935.	1936.	1937.	1938.	1939.	1940.
20,522	10,107	4,296	2,543	1,368	1,002	247

million was carried out in 1935, and continued, including re-vaccination, during 1936–39 (Table 155).

The results are necessarily difficult to interpret, since it is impossible to know what fall in mortality would have occurred in the absence of vaccination. The fall, however, in this instance was remarkably rapid, and the figures taken in conjunction with those of Table 154 suggest strongly that vaccination played a not unimportant part.

In Madagascar a living vaccine has been employed, made from a strain E.V., which had become attenuated by monthly subculture for 4 years (Girard 1936). From 1921, when plague was introduced, the cases rose from 187 to reach 3,880 in 1933 (Girard and Robic 1938, 1942). In 1935 vaccination was begun, and was followed by a fairly rapid reduction in the incidence and mortality rate (Table 156).

TABLE 156

CASES AND DEATHS FROM PLAGUE IN MADAGASCAR (Robic 1938).

Year.	Number of Cases.	Number of Deaths.	Remarks.
1933–34	3,493	564	
1934–35	3,605	510	
1935–36	3,035	507	First vaccination campaign
1936–37	1,376	206	Second vaccination campaign
1937–38	596	85	Third vaccination campaign

As in Java, the fall after vaccination was started appears to have been greater than would have been expected in its absence.

Grasset (1941) in South Africa uses a mixture of the Tjiwidej and E.V. strains for the preparation of a living vaccine. The dose recommended is 1,000 million organisms. This gives rise to a moderate local swelling with some tenderness, but to little or no constitutional reaction.

It is impossible to assess the comparative value of dead and living vaccines in the prevention of plague. Nothing but a simultaneous trial of the vaccines on the same population, together with a proper control group of uninoculated subjects, is likely to supply us with the necessary information. There is little doubt, however, that provided due care is exercised to prevent contamination, the living avirulent vaccine can be employed without danger for the inoculation of human beings.

Serum Treatment.—A number of sera have been used in the treatment of human plague. Rowland (see Report 1911, p. 11) stated that serum prepared by immuniz-

ing horses with a solution of "nucleoproteins" from the plague bacillus had definite curative properties in rats. A report on the use of Yersin's, Haffkine's, Lustig's, Terni's, and Brazil's sera was published by the Government of India (Haffkine 1905); none of them affected the mortality of the disease. The English Plague Commission likewise obtained no evidence that serum treatment was beneficial (Report 1912, p. 326). More recently, both Girard (1936) and Pirie and Grasset (1938) have found that serum prepared by the inoculation of horses with living avirulent organisms is considerably more potent, as judged by animal tests, than that prepared from dead organisms. In human beings Girard (1941) states that 65 per cent. of patients suffering from bubonic plague recover under serum treatment. Of 70 patients treated with serum by Wagle, Sokhey, Dikshit and Ganapathy (1941), 71·5 per cent. recovered as against only 47·6 per cent. of 82 control patients receiving the routine iodine treatment. The serum was given in doses of 20 ml. intravenously and 20 ml. subcutaneously every day for 2–5 days. Alarming reactions may follow intravenous administration, and it might be better to give more frequent injections intramuscularly.

Chemotherapy.—Schütze (1939*b*), working with white rats and white mice, found that sulphapyridine had a protective effect similar to that of serum. In the series of patients just referred to, Wagle and his colleagues (1941) treated 53 patients with sulphapyridine and 32 patients with sulphathiazole in 0·5 gm. doses every 4 hours up to a maximum of 7 days; the recovery rates were 75·5 and 84·4 per cent. respectively. The results might have been better if a larger dosage had been tried. Neither serum nor sulphonamide seems to be of therapeutic value in pneumonic plague (Girard 1941, Wagle *et al.* 1941). According to Wayson and McMahon (1944), sulphadiazine is of undoubted therapeutic value in rabbits and guinea-pigs experimentally inoculated with plague. On the whole the evidence suggests that sulphathiazole and sulphadiazine are among the most active of the sulphonamide compounds.

PASTEURELLOSIS OR HÆMORRHAGIC SEPTICÆMIA OF ANIMALS

The observations of Bollinger and of Kitt in 1878 on an epidemic disease affecting wild hogs, deer, and later cattle in the neighbourhood of Munich constitute the first work of importance on a group of diseases attacking several species of animals, and known collectively as Hæmorrhagic Septicæmia. Kitt was successful in isolating the causative organism and in transmitting the disease to mice and pigeons. A similar organism was obtained by Pasteur in 1880 from fowl cholera, by Loeffler in 1882 from swine plague, by Poels (1886) from septic pleuropneumonia of calves, and by numerous workers during the next few years from diseases in other animals. In 1901 Lignières proposed to unite all these affections into one group under the name of Pasteurellosis, and to call the infecting organisms *Pasteurella*. He divided this group into 6 sub-groups according to the species of animal attacked:

(1) Avian type, attacking hens (fowl cholera), other birds, and rabbits.

(2) Porcine type, giving rise to swine plague (*Schweineseuche, Pasteurellose du porc*).

(3) Ovine type, affecting sheep (*pneumo-entérite, lombriz*), and infectious pneumonia of goats.

(4) Bovine type, attacking cattle (*Wild- und Rinderseuche, septicémie hémorragique des bovidés, pneumo-entérite du bœuf, barbone* of buffaloes, septic pleuropneumonia of calves, and *entiqué*).

The 5th and 6th sub-groups comprised equine influenza and canine distemper respectively, neither of which is actually due to *Pasteurella*.

This classification is incomplete and has little to recommend it; there is no place in it for pasteurellosis of the mouse, the rat, the reindeer and other animals that suffer naturally from the disease. Moreover it has now become clear that all true *Pasteurella* infections are manifestations of one infective process—Septicæmia hæmorrhagica. The causative organism is apparently the same throughout; and there is no means by which its animal origin can be ascertained with certainty.

The clinical manifestations of pasteurellosis vary according to the animal attacked; in some animals two or more forms of the disease have been recognized. Generally it runs an acute course with death in the space of a few hours to a few days. The mortality is high, 70–100 per cent. (Brimhall and Wilson 1900, Rice 1926). Post mortem, the main lesions are found in the viscera. Petechial hæmorrhages are common especially in the pleura, endocardium, and kidneys; and larger hæmorrhages may be scattered through the submucous connective tissue and lymphatic glands (Brimhall and Wilson 1900). In the pulmonary form the mucosa of the trachea and bronchi is congested; the lungs are hyperæmic and show diffuse or patchy consolidation; the pleura is covered with coagulated fibrin, and there is a fibrinous or purulent exudate in the pericardium (Poels 1886). The peribronchial and mediastinal lymph glands are swollen, and on section are moist and red. Congestion of the kidneys is noticeable, particularly in swine; microscopically there is epithelial necrosis of the tubules (Magnusson 1914). In the intestinal form the most noticeable feature is acute hæmorrhagic enteritis, with sometimes bloody mucus in the intestine (Rice 1926). The spleen and liver usually show little or no change (Voges 1896), but they are frequently covered with fibrino-purulent exudate, similar to that in the peritoneal cavity (Mørch and Krogh-Lund 1931). Microscopically the small, regular, oval, Gram-negative, bipolar-staining bacilli are found in enormous numbers in the blood and viscera. In the cow the udder may occasionally be affected (Lovell 1939).

The method by which the disease spreads is not altogether clear. Hueppe (1886) regarded it as a ground infection like anthrax, but the very low resistance of the organisms to inimical agencies would seem to exclude this. Magnusson (1914), who observed a large epidemic amongst reindeer in Sweden, suggested that it was spread by a sucking insect. This suggestion finds some support in the observations of Daubney, Hudson, and Roberts (1934), who brought evidence to show that the disease in cattle could be carried by the flea *Ctenocephalus felis* Bouche. Recently the belief has been gaining ground that it is primarily a respiratory infection. The organisms have been found on the mucosa of the mouth and in the nasopharynx of normal swine (Uhlenhuth and Haendel 1913). De Kruif (1921, 1922*a*, *b*, 1923), working with rabbits suffering from snuffles—a chronic form of the disease—observed the organism in the nose of a large proportion of normal animals. Webster (1924*a*, *b*) found that preceding an outbreak there was a rise in the normal carrier rate. The susceptibility of rabbits varied greatly, some being highly resistant, others succumbing with ease. Similar variation in the susceptibility of fowls to natural and experimental infection has likewise been

noted by Rice (1926). These observations suggest that natural infection occurs through the nose, and that it is dependent on the presence of carriers.

Pasteurella Infections in Man.—Though several authors have described diseases in man that they consider to be due to *Pasteurella* infection, few of the accounts carry conviction. Reviewing the literature, Regamey (1939) (see also Lévy-Bruhl 1938) has traced ten cases that were probably, and six cases which he thinks were certainly, due to this organism. Of the six genuine cases, three were characterized by pleurisy, two by meningitis, and one by a local lesion following the scratch of a cat. Subsequent cases have been recorded by Foerster (1938), Mulder (1938), Boisvert and Fousek (1941) and Ludlam (1944). Allott and his colleagues (1944) record six cases, three following cat bites and three following dog bites. Three of the cases were complicated by osteomyelitis. Localized disease is commonly followed by recovery, but generalized cases have usually proved fatal. Infection may occur without accompanying illness; in our own experience, for example, an animal house attendant who carried *Pasteurella septica* in his nose for several months remained quite well.

Protection, Vaccination, Serotherapy, and Chemotherapy.

It was when working with chicken cholera that Pasteur observed a spontaneous diminution of virulence in a culture which he had left for some weeks at room temperature in contact with the air. This culture, on inoculation into fowls, proved harmless. When these fowls were re-inoculated shortly afterwards with a virulent culture, instead of dying of hæmorrhagic septicæmia they recovered rapidly after a brief indisposition.

The vaccines used at present for the prophylaxis of pasteurellosis are made chiefly from strains attenuated by heat or chemical agents. In some instances their use appears to have yielded satisfactory results (Brimhall and Wilson 1900, Chamberland and Jouan 1906, Hutyra and Marek 1912, Magnusson 1914). The work of Priestley (1936) seems to show the importance of using a vaccine prepared from virulent capsulated bacilli. To avoid destroying the antigenic properties of the capsule the organisms should be killed by heating at 56° C. for not more than 30 minutes. Immune sera prepared by injection of horses with living organisms or with body exudates are sometimes employed therapeutically (Schirop 1908). The most promising method appears to be combined active and passive immunization.

According to Cardoso, Reis and Nobuga (1939), sulphanilamide has a protective effect in chickens experimentally inoculated with *Pasteurella*.

Other Diseases Associated with Pasteurella or Pasteurella-like Organisms.

Pasteurella is a common secondary invader in many diseases of animals. It has been found especially in swine fever, in which it gives rise to severe pulmonary complications, in influenza of horses (Lignières 1901), and occasionally in canine distemper (Lignières 1901), in roup (Bushnell 1923) and diphtheria of fowls (Chamberland and Jouan 1906).

The so-called " de Aar disease," described by Pirie (1929) and Mitchell (1930), affecting the veld rodents of South Africa, was probably due to a genuine *Pasteurella* infection. On the other hand the contagious pneumonia of sheep, recorded by Dungal (1931) in Iceland, was caused by an organism differing in several respects from *Past. septica* (see Chapter 32), as was also the pyogenic disease of sheep described by Jowett (1931).

A number of outbreaks in fowls (Higgins 1898), geese (Frosch and Bierbaum 1909), rabbits (Kraus 1897*a*, Kurila 1909, van Saceghem 1922), and guinea-pigs (Busson 1921) have been ascribed to infection with *Pasteurella*, which, from the records, were probably due to other organisms. There is still a disposition to treat the *Pasteurella* group as a convenient refuge for any small, Gram-negative bacillus whose identity has not been accurately ascertained. A genuine epizootic among guinea-pigs, however, has been described by Wright (1936).

PSEUDOTUBERCULOSIS

There are three or four diseases of animals known as pseudotuberculosis, which are caused by different organisms.

Pseudotuberculosis of Rodents.—In 1883 Malassez and Vignal described a disease in a guinea-pig that had been used for experimental inoculation, which was characterized by the presence of nodules histologically similar to those of tuberculosis, but containing zooglœal masses of coccoid bacilli. To this disease they gave the name zooglœal tuberculosis. A similar organism was found by Dor (1888), Charrin and Roger (1888), Nocard (1889), and Zagari (1890) in guinea-pigs dying either naturally or after inoculation with pathological material. Preisz (1894), who made a comparative study of these organisms, concluded that they were identical with a bacillus described by Pfeiffer in 1890 under the name *B. pseudotuberculosis rodentium*, now known as *Past. pseudotuberculosis*.

The disease attacks guinea-pigs chiefly, and to a less extent rats. In Germany cats appear to be not infrequently infected (Pallaske and Meyn 1932). Sporadic cases of the disease are observed in mice, rabbits, hares, pigeons, turkeys, and canaries (Pallaske 1933). Infection appears to occur by the alimentary tract. Post mortem in guinea-pigs, there are rounded greyish-white spherical nodules up to 2 or 3 mm. in diameter, distributed chiefly in the spleen, liver, and lungs. The nodules are well defined, often protrude from the surface, and on section appear creamy or caseous. Enlarged caseous mesenteric glands are generally present. Microscopically the lesions contain large numbers of short, coccoid or ovoid, bipolar-stained Gram-negative bacilli, which can be readily cultivated on agar (see Chapter 32). The disease can be reproduced experimentally in large numbers of different animals and birds (see Pallaske 1933). On injection into guinea-pigs, rabbits, rats, or mice the bacilli prove fatal in 1 to 3 weeks, depending on the dose used and the site of injection. At necropsy after intramuscular inoculation there is a caseous local lesion, enlargement of the regional lymphatic glands, and nodules in the spleen, liver, and lungs. Microscopically, the bacilli are numerous in the local lesion and glands.

Pseudotuberculosis of Mice.—This disease is due to a short Gram-positive diphtheroid bacillus, *C. murium*, described independently by Bongert (1901) and Kutscher (1894), (see Chapter 17).

Pseudotuberculosis of Sheep.—This disease has been reported in Europe, America, and Australia. It is caused by a short, non-motile, Gram-positive diphtheroid organism, known as the Preisz-Nocard bacillus or *C. ovis* (Preisz 1894). The same organism appears to be responsible for ulcerative lymphangitis of horses and perhaps for contagious acne of horses (Hutyra and Marek 1912) (see Chapter 17).

Pseudotuberculosis of Pigs.—Both Chaussé (1916) and Velu (1922) describe a disease of pigs under the name of pseudotuberculosis. The peri-pharyngeal lymph nodes appear to be chiefly affected, and the caseous lesions produced resemble those of true tuberculosis very closely. Visceral lesions may or may not be present. The cause of the disease is unknown.

Pseudotuberculosis of Man.—Topping, Watts and Lillie (1938) record a case of human infection with *Pasteurella pseudotuberculosis*. It is said to be the fifth authentic report in medical literature. Topping's case was characterized by an influenzal type of onset, fever, abdominal tenderness, neck rigidity, and later jaundice. Death occurred after 16 days. At autopsy the liver was found to be enlarged and studded with necrotic foci 1–10 mm. in diameter; the spleen was likewise enlarged and showed a diffuse lymphoid hyperplasia. An organism was isolated from the blood before death and from the liver at post mortem which was regarded as being identical with *Past. pseudotuberculosis*. Since, however, no adequate serological or pathogenicity tests appear to have been made, its exact identity must remain in doubt.

CHAPTER 74

ACUTE RESPIRATORY INFECTIONS

One at least of the diseases dealt with in this chapter—epidemic influenza—would be more correctly placed among the virus diseases, and it is highly probable that the same applies to the common cold. Both these infections are, however, so closely connected from the clinical point of view with other respiratory diseases that it is convenient to take them out of their proper order. On the other hand, the virus pneumonias are better treated in Chapter 85, since the various agents supposed to be concerned in their causation must be discussed in relation to the lymphogranuloma-psittacosis group of filtrable viruses.

The Common Cold

Studies that have been recorded in recent years, and particularly those of Dochez and his colleagues (Shibley, Mills and Dochez 1929, Dochez, Shibley and Mills 1930, Dochez, Mills and Kneeland 1931*a*, *b*, 1932, 1933, 1936) have greatly strengthened the view advanced by Foster (1917) that the infectious common cold is a virus disease (see also Long *et al.* 1931, Powell and Clowes 1931).

Since we have as yet no satisfactory evidence that any of the ordinary laboratory animals are susceptible to infection with this virus, resort has been made to the higher apes, or to human volunteers; and this has seriously limited the scope of the experiments. One of the great difficulties that has to be overcome in work of this kind is to eliminate the risk of natural contact infection.

Dochez, Shibley and Mills (1930) recorded the transmission of the common cold to anthropoid apes, and to human volunteers, by the intranasal instillation of filtered washings from cases of the disease. Long and others (1931), using human volunteers, succeeded in several instances in inducing an acute cold with filtered nasal washings, and in transmitting it from one subject to another in series. Dochez, Mills and Kneeland (1931*a*, *b*) recorded the cultivation of the virus in Tyrode solution containing minced chick embryo, and the production of a cold in two of three volunteers with a fifteenth subculture (see also Dochez, Mills and Kneeland 1936); and Powell and Clowes (1931) have recorded similar findings.

It is probable that many points in the problem of the ætiology of the common cold—the existence of one or more types of virus, the relation of the cold virus to the influenza virus, and so on—will await the discovery of a more convenient experimental animal than man, or the anthropoid ape. In the meantime we are justified in accepting the view that the infectious common cold is a virus disease, at least as the best working hypothesis; and, for this reason, earlier observations that sought to trace a causal relationship between various bacterial inhabitants of the nasopharynx and this particular disease have become of minor interest, and may be briefly summarized.

The available records are indeed by no means consistent (see Williams, Nevin and Gurley 1921, Shibley, Hanger and Dochez 1926, Noble, Fisher and Brainard 1928, Shibley, Mills and Dochez 1929, Burky and Smillie 1929). Taking them as a whole it may fairly be said that they fail to establish any case for a consistent significant change in the bacterial flora of the nasopharynx in association with the onset of an acute cold.

In an investigation undertaken in Manchester during the period 1926–28 (see Report 1930) a nasopharyngeal swab was taken each month from 100 persons who volunteered to assist in the inquiry. Additional swabbings were taken from these persons whenever they contracted a cold. Data were thus available for a considerable number of swabbings, taken from the same persons at times when they were suffering from a cold, and at other times when they were not. The figures referring to the frequency of *H. influenzæ*, hæmolytic streptococci and the pneumococcus, are set out in Table 157. They refer only to those persons who contracted a cold during the period of observation ; and they do not include the results obtained in cases which, on clinical grounds, were diagnosed as influenza.

TABLE 157

	With Colds (110 Swabs).		Without Colds (1,731 Swabs).	
	Number +.	Per cent.+.	Number +.	Per cent. +.
H. influenzæ	52	47·27	984	56·85
Hæmolytic streptococci .	19	17·27	229	13·23
Pneumococci	30	27·27	446	25·77

It will be noted that, while pneumococci and hæmolytic streptococci were slightly more frequent in those that had colds, than in those that had not, the difference is slight and insignificant ; *H. influenzæ* was more frequently isolated at times when no sign of a cold was present. It should be added that most of these colds were trivial ; and it is probable that the factors of type and severity of infection are largely responsible for the divergent findings recorded by different workers. The " common cold " is, in fact, a disease that is impossible to define on clinical grounds. In a later investigation in London (Straker, Hill and Lovell 1939) no difference was found in the incidence of pneumococci, hæmolytic streptococci, and Pfeiffer's influenza bacilli between normal persons and patients suffering from a cold. Pneumococci and influenza bacilli, however, tended to be slightly more frequent a week after the onset of a cold than at the beginning. It is probable that these organisms are often responsible for muco-purulent inflammation of the nasal mucosa and the adjacent sinuses. In the particular case of the influenza bacillus, Dochez, Mills and Kneeland (1932) have noted the replacement of the ordinary " rough " type by the " smooth " virulent type of Pittman (see Chapter 33) following the induction of acute colds in apes with a filtrable virus.

Prophylactic Immunization against the Common Cold.

No virus-containing preparation is as yet available for active immunization. In view of what has been said above we should not expect that the injection of a bacterial vaccine, containing pneumococci, influenza bacilli, hæmolytic streptococci and so on, would have any effect on the incidence of colds, since the causal organism is not included in it. There is scarcely more reason to suppose that it would in any way diminish the severity of colds or lessen the chances of secondary infection, since the bacterial species of which it is composed are antigenically highly heterogeneous, and only a few arbitrarily selected types of each species can be included. The results of adequate clinical trials are in accord with immunological expectations.

Von Sholly and Park (1921), using a mixed vaccine of the ordinary type, inoculated 1.327 persons and kept them under observation, together with 3,025 uninoculated controls, from September 1919 to May 1920; during this period 57·7 per cent. of the inoculated and 38·2 per cent. of the uninoculated developed colds. Jordan and Sharp (1921) observed 448 inoculated persons and 461 uninoculated controls from November 1919 to June 1920; 54·9 per cent. of the inoculated and 51·6 per cent. of the uninoculated developed colds. Ferguson, Davey and Topley (1927) observed 138 inoculated persons and 148 uninoculated controls from November 1924 to May 1925; 78·3 per cent. of the inoculated and 70·3 per cent. of the uninoculated developed colds. Brown (1932) observed 80 inoculated persons and 82 uninoculated controls from November 1929 to June 1930; the inoculated contracted 1·85 colds per person during this period, the uninoculated 2·17. Further mass immunization trials with vaccine given subcutaneously, orally or intranasally have been recorded by other workers (Diehl, Baker and Cowan 1938, Siegel *et al.* 1943, McGee *et al.* 1944, Cowan and Diehl 1944, Hague 1944—see also Report 1944*c*)—likewise with negative results. It is most unfortunate that countenance should be given to the use of a vaccine so clearly devoid of protective power, and all those concerned with public health should set their faces resolutely against a practice which, though financially profitable for the makers of the vaccine, is without any scientific support.

With very few exceptions, the results of properly conducted trials are equally unfavourable to the suggestion that immunization with an " anticatarrhal " vaccine diminishes the severity of colds, or lessens the frequency of secondary infections.

It may be added for the sake of historical interest that the preparation *patulin*, a product of the mould *Penicillium patulum*, which was introduced for the treatment of colds (see Raistrick 1943, Gye 1943, Hopkins 1943), was found, when submitted to a carefully controlled trial, to be without therapeutic effect (Report 1944*a*).

Epidemic Influenza

The recent solution of the problem of the ætiology of influenza by Laidlaw and his colleagues (see Smith, Andrewes and Laidlaw 1933) will certainly stand as one of the important landmarks in the history of preventive medicine.

This disease has presented the epidemiologist with one of his most fascinating and provoking problems. It has a long and puzzling history; and, within recent years, it has been the reigning killing disease of adult life; nor is there any likelihood that its reign will end apart from some effective method of prophylaxis. The pandemic of 1918–19 was one of the great pestilences of mankind, destroying more lives in a few months than did the Great War in 4 years. Those who are interested in that pandemic and in the lessons to be learned from it may be referred to the report issued by the Ministry of Health (Report 1920). We may note that influenza is one of those diseases that seems to confer only a transitory immunity, in the sense that repeated attacks are common. We may also note that its epidemiological study has, up to the present time, been rendered unusually difficult by the lack of precision in its clinical diagnosis. There is little difficulty in telling when we are faced with an *epidemic* of influenza; but sporadic cases, and even minor outbreaks, of acute febrile diseases are very apt to receive this particular label without any very definite reason. The clinical syndrome that justifies a diagnosis of influenza is, indeed, singularly difficult to define (see Stuart-Harris *et al.* 1938). It is probable that, with the knowledge we now possess, the clinician and bacteriologist between them will be able to place this problem on a far more satisfactory footing.

The Ætiology of Influenza.

In view of our present knowledge the long controversy as to whether epidemic influenza was, or was not, caused by *H. influenzæ*, described by Pfeiffer in 1892, has lost all but historical interest.

Those interested may be referred to the monograph by Kristensen (1922). We may summarize the extensive bacteriological literature by noting that, while there is ample evidence that the influenza bacillus is very frequently present in the nasopharynx of those suffering from the disease (see for instance Pritchett and Stillman 1919, McClelland 1919, Park 1919, Duval and Harris 1919, Schorer 1919, Medalia 1919, Dick and Murray 1919, McIntosh 1922), and though its distribution in the tissues, as revealed by post-mortem examination, makes it clear that it often plays a part in the disease as it appears in man (see Fildes and McIntosh 1920, McIntosh 1922), its curious absence in certain epidemics, particularly in the summer of 1918, had raised serious doubts as to its primary ætiological rôle before the view that influenza was a virus disease had been clearly established (see Mandelbaum 1918, Selter 1918, Messerschmidt *et al.* 1919, Leichtentritt 1918, Kristensen 1922).

The virus theory of influenza was, of course, held quite widely as a possible working hypothesis, before the problem was attacked by Laidlaw and his colleagues, and there had been occasional reports of the transmission of an influenza-like disease to apes or to human volunteers with filtered washings from influenzal patients; but none of these experiments was on such a scale as to establish any definite conclusion.

The most important contribution to the influenza problem, prior to the original report of Smith, Andrewes and Laidlaw (1933) was the work of Shope on influenza in swine, and this will be considered in a later section.

In view of their great importance the observations of Laidlaw and his colleagues must be discussed in some detail.

In their original communication Smith, Andrewes and Laidlaw (1933) showed that a characteristic febrile disease could be induced in ferrets by the intranasal instillation of filtered nasal washings from a human case of epidemic influenza. This disease was transmissible in series, from ferret to ferret, either by natural contact or by the intranasal instillation of filtered material. Ferrets that had recently recovered from the disease were resistant to re-infection, and their serum contained protective antibodies in high concentration. In this report it was also noted that Shope's swine influenza virus produced in ferrets a disease indistinguishable from that produced by the human virus, and that there appeared to be an immunological relationship between the two types. These observations were later confirmed and extended (see, also, Shope 1935, Francis and Shope 1936). Shope (1934*b*), who had successfully repeated the experiments of Smith, Andrewes and Laidlaw, found that the swine influenza virus when injected intranasally into ferrets under ether anæsthesia produced pneumonic lesions in the lungs, and Andrewes, Laidlaw and Smith (1934), using a similar technique, were able to induce a fatal pneumonia in mice, with both the human and swine viruses. Francis (1934) isolated a strain of the human virus from cases of influenza in Puerto Rico, and this virus and other strains isolated later in New York and Philadelphia were found to be immunologically identical with the original English strain, and with other strains isolated in England during the winter and early spring of 1934–35 (Laidlaw 1935, Andrewes, Laidlaw and Smith 1935, Francis and Magill 1935*a*). An immunologically identical virus has since been isolated from epidemics of influenza in

Australia (Burnet 1935*a*), Alaska (Pettit, Mudd and Pepper 1936), and other parts of the world (see Mote 1941). This virus is now generally referred to as the influenza A virus. Failure to find it in some outbreaks led to the suspicion that more than one type of virus might exist. Variants of the A virus were described by Magill and Francis (1936); and later, Magill (1940) and Francis (1940*b*) independently discovered a new type, antigenically distinct, which is now known as influenza B. There is reason to believe in the existence of at least one more type, since Lennette and his colleagues (1941), in a study of 19 separate outbreaks of influenza, could find no evidence of either A or B virus in over 30 per cent. of the cases examined.

Laidlaw (1935) suggests that the swine influenza virus may represent the 1918–19 human virus which has become acclimatized to swine. This tentative hypothesis is based in part on the proved immunological relationship, but not identity, of the two viruses, in part on the fact that, while neutralizing antibodies to the human virus were found in most human sera, antibodies to the swine influenza virus were regularly present in adult human sera, but were wholly absent from the sera of a small sample of children (Andrewes, Laidlaw and Smith 1935). Similar observations have been recorded by Francis and Magill (1936), and by Shope (1936). The correctness of Laidlaw's interpretation is rendered doubtful by the finding that influenza A virus can give rise to antibodies against the swine influenza virus, and that a similar age distribution of antibodies as that found 15 years after the 1918–19 pandemic seems to exist at the present time (Horsfall 1943).

The evidence in favour of the virus causation of influenza has been summarized by Andrewes (1937). Considerable difficulty has been experienced in the reproduction of the disease in man with laboratory strains of the A type of virus. Successful results have been obtained, but only irregularly. One reason for this may be that many adults contain neutralizing antibodies in their serum. The higher the antibody titre, the greater, on the whole, is the resistance of the subject to infection, though it is clear that other factors influence the result (see Horsfall 1943). Resistance to Type B seems to be less general; and in one trial Francis and his colleagues (1944) appear to have been able to reproduce the disease in practically every subject tested.

How influenza infection is kept going from one epidemic to another is doubtful, but there is some evidence to suggest that chronic carriers may exist (Taylor and Dreguss 1940).

Properties of the Virus.—There has been some dispute over the size of influenza A virus. Elford, Andrewes and Tang (1936), using the gradocol membrane technique, found it to fall between the limits of 80 and 120 mμ; and Elford and Andrewes (1936), using the centrifugation technique, estimated it at between 87 and 99 mμ. Chambers and Henle (1943), however, concluded from centrifugation experiments that it was only 10 mμ in diameter. Stanley (1944), who studied the reason for this discrepancy, showed that the behaviour of the influenza virus in dilute solutions of electrolyte was variable, and he brought evidence to show that the real size was probably about 70 mμ. Taylor and his colleagues (1943), as the result of centrifugal separation of Virus A, confirmed Elford and Andrewes' observations, finding the mean particle size to be 77·6 mμ. This estimate is identical with that reached by Sharp and his colleagues (1944), who examined the A virus by the electron microscope, and concluded that the particles were kidney-shaped and had a mean diameter of 77·6 mμ. Lauffer and Stanley (1944), however, obtained a value by the electron microscope method (Fig. 291) of

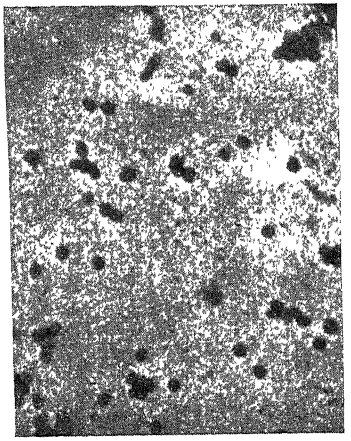

FIG. 291.—Electron micrograph of influenza virus Type A (× 17,750). (Kindly supplied by Dr. W. M. Stanley.)

115 mμ, and by the centrifugation technique of 80 mμ. They regard the discrepancy between these two findings as due to a high water content of the virus particles, and they suggest that the real value is about 100 mμ. The B virus was found by Sharp and his colleagues (1944) to be circular or ovoid in shape, and to have a mean particle diameter of 97·3 mμ. The swine influenza virus, according to Taylor and his colleagues (1944), resembles in size Virus A, being about 78–81 mμ in diameter.

The virus can be grown in tissue culture (Francis and Magill 1935*b*), and on the chorio-allantoic membrane of the developing chick embryo (Burnet 1935*b*). Though these observations were made on strains adapted to the mouse or the ferret, success was later recorded in direct culture experiments from human material. It is interesting to note that inoculation of the chick embryo with Virus A interferes with the growth on subsequent inoculation of Virus B or the swine influenza virus. Any one of these three viruses, in fact, prevents the growth of either of the other two—subject to certain time and qualitative relationships (Ziegler and Horsfall 1944, Ziegler, Lavin and Horsfall 1944) (see also Chapter 55, p. 1236).

The antigenic structure of the influenza virus is still the subject of detailed observation. The A and B viruses are antigenically distinct, but within each type there appears to be considerable heterogeneity (see Mote 1941). Variants of the A virus have been described by Magill and Francis (1936), Magill and Sugg (1944), and Friedewald (1944), and variants of the B virus by Eaton and Beck (1941) and Gordon (1942). Some of the Type A strains seem to be related more closely to the British swine influenza viruses than to the American swine influenza virus (Glover and Andrewes 1941, Hudson *et al.* 1943). According to Burnet (1942), the human virus, though not antigenically related to the Newcastle disease virus of chicks, nevertheless behaves like it in many respects. Studies have revealed the existence of two antigenic fractions in the influenza virus: (*a*) a fraction intimately associated with the virus particle and readily adsorbed by fowl red blood corpuscles, and (*b*) a soluble fraction which remains in the supernatant fluid of centrifuged suspensions, and which is not adsorbed by red corpuscles. The body antigen appears, by the complement-fixation test, to be more specific than the soluble antigen (see Lennette and Horsfall 1940, Friedewald 1943).

According to Knight and Stanley (1944), the purified virus is inactivated promptly by 5 per cent. phenol, in a week by 0·5 per cent. phenol, and in a month by 0·1 per cent. phenol. The effect of other disinfectants has been studied by Dunham and MacNeal (1944).

A most interesting property of both types of influenza virus—also shared by the Newcastle disease virus of chickens (Burnet 1942)—is their ability to agglutinate the red blood corpuscles of fowls and certain mammals (Hirst 1941, 1942, Hirst and Pickels 1942). Provided the strains are fresh and fully pathogenic, the agglutination titre runs parallel to the mouse lethal titre. Agglutination is inhibited specifically by immune serum, the degree of inhibition affording an index to the ability of the serum to neutralize virus. The test can therefore be used diagnostically for detecting the presence either of virus or of antibodies (see also Miller and Stanley 1944).

Burnet and Bull (1943) found that freshly isolated strains of Virus A agglutinated guinea-pig red corpuscles to a much higher titre than fowl corpuscles, but that after passage in series through chick embryos they agglutinated both types of corpuscles to much the same extent. Other changes likewise occurred as the result of passage, closely reminiscent of variation in bacterial cultures. Observations suggested that the degree of agglutination of the red corpuscles of a particular species of animal, including man, afforded a good index of the degree of susceptibility of that species to infection.

Diagnosis.—The laboratory diagnosis of influenza is made by demonstration of the virus in the nasopharynx, or of complement-fixing or neutralizing antibodies in the blood serum. The presence of the virus may be established by the injection of garglings or sputum, taken during the first two or three days of the disease, into the nose of a ferret. If virus is present, the animal develops a febrile illness after about 48 hours, accompanied by rhinitis. Passage of the virus through anæsthetized ferrets results in the production of pneumonia, which is often fatal. Alternatively, the nasopharyngeal washings of the patient may be injected intranasally into mice or into the amniotic sac of the developing chick embryo. Neither of these methods, however, is reliable, since many strains of virus fail to produce obvious lesions on first inoculation. Complement-fixing or neutralizing antibodies may be demonstrated in the patient's serum within about a week of the beginning of the disease. By the use of suitable control strains and sera the type of infecting virus to which neutralizing antibodies have appeared may often be determined by the intraperitoneal injection of mice. It must be remembered, however, that there is considerable antigenic variation among different strains, and clear-cut results are not always obtained (see, for example, Magill and Sugg 1944).

Immunization.—The problem of immunization against the influenza virus is clearly of primary importance. If we could induce an effective active immunity in man we should be in a position to eliminate the disease, or reduce it to negligible proportions. It is possible that passive immunization, by the injection of an antibody-containing serum, might exert some therapeutic effect in an established case; but this method, even if successful, should clearly be regarded as a second and subsidiary line of defence.

According to the observations of Smith, Andrewes and Laidlaw (1935), ferrets that have recovered from an attack of the virus disease are, for a time, completely resistant to infection. This solid immunity persists for about 3 months, and then gradually wanes. Ferrets with a waning immunity still show the presence of protective antibodies in their blood, although the nasal mucosa has become susceptible to re-infection; and, when it is re-infected, the circulating antibodies fail to protect the animal against a general febrile reaction. The position in regard to active immunization, apart from the production of an attack of the disease, is curious and interesting. The ferret is not susceptible to the injection of the living virus otherwise than by its intranasal instillation or by some other method of introduction directly into the respiratory tract. Animals inoculated subcutaneously, intradermally, intraperitoneally, intramuscularly, intratesticularly or intracerebrally show no sign of illness. Such injections, particularly if frequently repeated, lead to the appearance of protective antibodies in the circulating blood; but the appearance of these antibodies is not associated with any effective resistance to infection by the intranasal route. This clearly suggests that the local con-

ditions in the nasal mucosa are of predominating importance. This is borne out by the observations of Burnet, Lush and Jackson (1939) and of Francis (1940*a*), who have demonstrated the presence in the serous nasal secretion of normal human beings of an agent capable of neutralizing the influenza A virus. According to Francis, this substance appears to be none other than specific neutralizing antibody, but whether it is derived wholly from the serum antibody is still doubtful. So far, attempts to induce immunity by the intranasal injection of killed or inactivated virus have failed, though the direct instillation of antibody into the nose has been shown to be of greater protective value in mice than much larger quantities injected into the blood stream (see Horsfall 1943).

If a ferret that is in the stage of waning immunity is injected subcutaneously with living virus, its immunity may be reinforced, so that it becomes again completely resistant to intranasal infection. Immunization by the subcutaneous route is not therefore completely without effect; and this is also shown by the fact that the injection of living or formolized virus into normal ferrets, although it induces no effective immunity to re-infection by the intranasal route, lessens the frequency of lung lesions. A similar effect may be observed in mice. From animal experiments, therefore, it would appear that the most that has yet been accomplished on the lines of active immunization is the production of a partial immunity of a relatively low grade.

Numerous attempts have now been made in man to vaccinate against influenza (Francis and Magill 1937, Stokes *et al.* 1937, Horsfall *et al.* 1941*a*, *b*, Hirst *et al.* 1942, Burnet 1943, Henle *et al.* 1943, Francis *et al.* 1943, 1944, Report 1944). Virus inactivated by a variety of methods gives rise to the same specific antibodies as living virus. The rise in antibody titre after vaccination seems to be related to the pre-vaccination titre of existing antibodies as well as to the dose and quality of the vaccine. In general, the higher the antibody titre at the time of exposure to infection, the greater is the degree of resistance; though it is clear that the antibody titre is only one factor in determining this result. Since repeated attacks of influenza may occur under natural conditions, it is hardly to be expected that more than a partial degree of transient immunity is likely to result from vaccination. This has been strikingly demonstrated by Francis and his colleagues (1944), who were able to produce two attacks of influenza within 4 months in human subjects inoculated intranasally with the same living strain of Type B virus. The second attacks were less severe than the first, but the fact that they occurred at all showed that the increased resistance following the first attack was relatively slight. If immunity even to the same type of virus is weak and transient, then protection against numerous different antigenic variants may prove very difficult to achieve.

In practice it may be found more expedient and economical to wait till an influenza epidemic has started, to determine the type of infecting virus, and then to inoculate the population at once with the corresponding vaccine. Antibodies are known to reach a high level within two weeks of inoculation, so that this method might succeed in lowering the case morbidity, even though it was given too late to protect those smitten early in the outbreak (see Hirst, Rickard and Friedewald 1944). (For preparation of influenza virus vaccine, see Stanley 1945.)

In regard to passive immunization, it has proved possible to produce an anti-influenzal horse serum that contains neutralizing antibodies to relatively high titre (see Laidlaw, Smith, Andrewes and Dunkin 1935). This serum, when injected

intraperitoneally into mice in relatively large doses, significantly increases their resistance to the intranasal injection of virus, under light ether anæsthesia, 45 minutes later. It also leads to a reduction in percentage mortality when injected intravenously or intraperitoneally into mice 24–48 hours after the intranasal instillation of virus. Better protection can be obtained with much smaller doses injected intranasally prior to nasal infection. Apparently successful attempts to prevent the development of influenza in human beings during an epidemic by inhalation of vaporized antiserum have been recorded by Smorodinzew and his colleagues (1940), but it is as yet too early to say whether this method will prove of value in practice.

In the past many attempts have been made to induce an immunity to influenza by the injection of a vaccine containing *H. influenzæ*. Clearly, such a procedure has no scientific justification and it is sufficient to note that, here again, adequate field trials are in accord with immunological expectations (see von Sholly and Park 1921, Jordan and Sharp 1921). For recent studies and reviews on influenza, see Stuart-Harris *et al.* (1938), Mote (1941), Horsfall (1943), and Stuart-Harris (1945).

Swine Influenza

We have referred above to Shope's observations on swine influenza (see Shope 1931*a*, *b*, 1932, 1934*a*, *b*, 1935, Lewis and Shope 1931). This disease first appeared, or was first recognized, in the United States in the autumn of 1918. It occurred in epidemic form in close association with the human pandemic of influenza, and it was at once suggested that there was some causal relation between them.

Shope (1931*a*, *b*) was able to show that the swine disease, in its characteristic clinical form, was caused by the associated effects of a filtrable virus and a hæmophilic bacillus, closely resembling the human influenza bacillus, to which he gave the name of *H. influenzæ-suis* (see Chapter 33). The virus alone caused a relatively trivial infection, unassociated with the pulmonary complications of the natural epidemic disease. The bacillus alone caused no detectable illness. As in the infection of ferrets with human influenza virus, the swine virus must be injected intranasally in order to produce any symptoms of disease ; injected intramuscularly it has no effect, either in inducing the mild virus disease or in rendering the animal sensitive to the intranasal instillation of *H. influenzæ-suis* (Shope 1932). The intramuscular injection of the virus does, however, render swine immune both to the mild virus disease and to the severe disease caused by the associated effect of the virus and the hæmophilic bacillus. Injections of *H. influenzæ-suis*, on the other hand, induce no immunity either to the virus or to the combined action of the virus and bacillus (Shope 1932). Inoculated into the developing chick embryo, the virus, in association with *H. influenzæ-suis*, gives rise to a mortality several times that caused by either agent alone. The two together cause destruction of the embryo lungs (Bang 1943).

As noted above, Shope (1934*b*) has shown that the swine virus, acting alone, will produce in ferrets a disease that is indistinguishable from that produced by the human influenza virus. He has also (Shope 1935) transmitted the virus to mice. The immunological relationship of the human and swine viruses, and its possible significance, have been discussed above. Antigenically, the American swine influenza virus strains appear to be homogeneous, whereas the British strains differ not only from the American strains, but to some extent from each other. They appear to occupy a position in some ways intermediate between the American

swine strains and the human Type A strains of influenza virus (Glover and Andrewes 1941).

The epidemiology of swine influenza has been illuminated by the studies of Shope (1941, 1943*a*, *b*). The disease tends to break out more or less simultaneously among separated herds of swine during the last three months of the year, particularly after some change in the weather, suggesting that the swine are already infected with the virus, but that some circumstance is needed to activate it. Shope has brought evidence to show that swine lungworms—*Metastrongylus elongatus* and *Choerostrongylus pudendotectus*—play an important part in the propagation of the disease. Lungworms taken from sick or from convalescent swine have been found to carry the virus, though in a masked form. The infected ova are coughed up by the pig and excreted in its fæces. They are swallowed by earthworms, in which they pass through three larval stages. The third stage is infective for swine. If the earthworm is then eaten by a pig, the larvæ penetrate the intestinal mucosa and migrate to the respiratory tract by way of the lymphatics and blood stream. After two further developmental stages, they finally become adult lungworms and occupy the bronchioles at the base of the diaphragmatic lobes. If infected earthworms are fed experimentally to swine, nothing happens; but if the animals are given multiple inoculations intramuscularly of living *H. influenzæ-suis*, some of them develop typical influenza—provided the experiment is carried out during the winter. Both the lungworms and the earthworms may remain infected for several months. The infected earthworms are probably eaten by swine at the time of the late spring and early autumn rains, when the worms come to the surface of the soil. The pig becomes infected in this way with the virus—still in the masked form. If at the time *H. influenzæ-suis* happens to be present, then it requires only some circumstance, such as a climatic or physical change—perhaps some weeks or months later—to activate the virus, allow it to penetrate the cells of the respiratory tract, and give rise to typical influenza.

Influenza in other Animals.

There are several other animal diseases, occurring in sporadic or epidemic form, to which the label "influenza" has been attached; "horse influenza" is an example. In the particular instance of the *horse* disease there is suggestive, if not conclusive, evidence that it is caused by a filtrable virus; and it is altogether probable that we shall find that several animal diseases are in fact due to infection with a virus of the influenzal type (see Discussion 1935). There is evidence, for example, that the disease of *calves* variously referred to as infectious pneumonia, calf influenzal pneumonia, and perhaps sometimes as scours, is due to a virus infection. The disease is widespread in Great Britain and in certain parts of the United States. It is characterized by fever, pneumonia, and in the later stages diarrhœa. The case mortality may be as high as 50 or 60 per cent. Animals killed at the height of the disease show a catarrhal enteritis and a bronchopneumonia. The disease can be transmitted by ground-up lung suspensions that have been filtered through a Berkefeld N candle or a Seitz EK disc (Lamont and Kerr 1939, Baker 1943). Baker has been able to transmit the infection to mice, and to reinfect calves with the pneumonic lungs of these animals. Calves that have recovered contain neutralizing antibodies in the blood serum.

Whooping Cough

H. pertussis, the causative organism of this disease, was first isolated and described by Bordet and Gengou (1906) (see Chapter 33). Its ætiological rôle is shown by the following observations. It can be isolated in the great majority

of cases during the first 2 weeks of the disease by the cough-plate or post-nasal swab method, or from the lungs at autopsy. It has seldom been demonstrated in normal persons, possibly because of the difficulty of detecting it when present in only small numbers. In the later stages of the disease and during convalescence specific antibodies make their appearance in the blood.

It may be added that Macdonald and Macdonald (1933) record the experimental production of whooping cough in two children with a culture of *H. pertussis*, and that Shibley and Hoelscher (1934) have reported the successful reproduction of the disease in the chimpanzee. A mild disease can be reproduced in rhesus monkeys (*M. mulatta*) by intranasal or intratracheal inoculation, and the organisms can be recovered from the lungs if the animals are killed within the following two weeks (North *et al.* 1940). The infections produced in ordinary laboratory animals, which bear no resemblance to the disease in man, are described in Chapter 33.

Whooping cough is mainly a disease of infancy and early childhood. Half of the deaths occur during the first year of life. Since the middle of last century the mortality of the disease has fallen greatly both in this country and in the United States (see Stocks 1942, Dauer 1943). The incubation period varies, but is round about 10 days. The duration of the catarrhal stage is usually about 11 days. The patient is infectious chiefly during this stage and to a less extent during the first week of the paroxysmal stage (see Lawson 1933).

Diagnosis.

The clinical diagnosis of whooping cough is often difficult and confirmation may be sought from the laboratory. During the catarrhal stage there is usually a leucopenia, but this changes during the paroxysmal stage to a leucocytosis with an absolute and relative lymphocytosis. The constancy of these findings is under dispute, but blood changes may be of help in cases seen too late for cultural methods to be of value.

Cultural.—As has been stated, *H. pertussis* can almost always be isolated from the sputum during the early stages of the disease (see Wollstein 1909, Chievitz and Meyer 1916). For several years the cough-plate method has been extensively used for diagnostic purposes, and has given satisfactory results. The patient is induced to cough directly on to a plate of Bordet-Gengou medium, and this is examined for the characteristic colonies after 48–72-hours' incubation (see Chapter 33).

Among reports on results obtained by this method are the following. Madsen (1925), in 914 cases, records 75 per cent. of positive isolations during the initial catarrhal stage, 61 per cent. during the 2nd week, 45 per cent. during the 3rd, 40·5 per cent. during the 4th, and 9 per cent. during the 5th. Sauer (1933*c*), in 400 cases, records 88 per cent. of positive isolations in the early catarrhal stage, 64 per cent. in the paroxysmal stage, and none in the late stages. Gardner and Leslie (1932), in 47 cases, record 67–75 per cent. of positive results in the first 3 weeks, 25 per cent. in the 4th and none thereafter. Kendrick and Eldering (1934), in 207 cases, record 78–84 per cent. of positive results during the first 3 weeks, 39 per cent. in the 4th and none in the 6th (see also Sugare and McLeod 1929, Sauer and Hambrecht 1930, Kristensen 1933, Straker and Westwater 1937, Donald 1938). It may be added that Kristensen (1933) records his failure to isolate *H. pertussis* from 500 healthy persons, and from 202 persons suffering from other respiratory diseases. Among 301 contacts, *H. pertussis* was isolated in 9 instances, and all these 9 persons subsequently developed whooping cough. Kendrick and Eldering (1934) and Wilcox

(1934) also record their failure to isolate the bacillus from any condition other than whooping cough.

More recently the post-nasal or nasopharyngeal swab has been introduced to avoid some of the inconveniences of the cough-plate method. Cultures from the swab are liable to be overgrown by other organisms, but if the swab is streaked on to a Bordet-Gengou plate over which a few drops of a suitable strength of penicillin have been spread, a high proportion of successful isolations may be achieved. Since Maclean (1937) first described this method, numerous observers have confirmed its value.

American workers (Bradford and Slavin 1940, Brooks and Bradford 1942, Miller *et al.* 1943) have used a very fine swab passed through the anterior nares till it reached the pharynx. In this country a bent swab passed through the mouth and up behind the soft palate has been preferred (Cruickshank 1944). Our own experience favours the latter method. In comparisons made by these different workers between the cough-plate and the swab methods, the results were consistently better when swabs were used, though a combination of the two methods gave the highest proportion of positive results.

Serological Tests.—The demonstration that specific complement-fixing antibodies appeared in the blood was first made by Bordet and Gengou (1906, 1907). The antigen employed is a suspension of *H. pertussis*.

These observations were confirmed by Winholt (1915) and by Chievitz and Meyer (1916), who showed that the reaction first becomes positive in the 3rd or 4th week, the proportion of cases reacting positively increasing up to the 8th or 10th week. The reaction usually becomes negative again in the course of a few months. Similar observations have since been reported by many observers (see Madsen 1925, Gundel and Schlüter 1933*a*, *b*, Donald 1938). There is general agreement that a small proportion of cases fail to develop a positive reaction at any stage in the disease.

Besides complement-fixing bodies, agglutinins appear in the serum. Their presence is best detected by a slide technique using living cultures of Phase I organisms. Evans and Maitland (1939), who compared the two methods, obtained a higher proportion of positive results by agglutination than by complement fixation.

A skin test has been recommended by Strean (1940) and by Smolens and Mudd (1943) for the diagnosis of susceptibility to infection (see also Strean and Grant 1940). The toxin is prepared by aqueous extraction of the frozen and thawed organisms or by acid extraction of a fresh culture. The value of this test is still in doubt.

It will be seen, therefore, that attempted cultivation by the cough-plate or the nasopharyngeal swab method is the diagnostic method of choice during the early stage of the disease, and before the characteristic paroxysmal cough has developed. It is at this stage that a bacteriological method of diagnosis is most helpful. In those cases in which the diagnosis remains in doubt for 3–4 weeks both cultural and serological tests may be employed. Where a laboratory diagnostic method is sought in a case of more than 4 weeks' standing the complement-fixation or agglutination test should be used.

Prophylactic Vaccination against Whooping Cough.

Reference to Chapter 33 will show that *H. pertussis* is antigenically of a single type. The conditions are, therefore, particularly favourable for active immunization with a vaccine of this organism. It has been noted, however, in the same chapter that this organism is very liable to undergo variation in the laboratory, and that the variant strains are of low virulence for laboratory animals and fail

to produce an effective immunity (see Leslie and Gardner 1931). It is therefore of the greatest importance that strains used for immunization should be fully virulent (Phase I of Leslie and Gardner); and the fact that this necessity has not always been allowed for must be borne in mind in assessing the published records of immunization in the field. Among the large-scale trials that have so far been reported are the following:

Madsen (1933) records trials made in the Faroe Islands during an epidemic in 1923–24, and in another epidemic in 1929. In the first epidemic the experience of 2,094 vaccinated subjects was compared with that of 627 unvaccinated controls. The incidence of the disease was the same in the vaccinated and unvaccinated, but it was milder and the death rate was lower among the vaccinated. In the preparation of the vaccine used in this trial several recent strains were used. In the epidemic of 1929, the vaccinated numbered 1,832, the unvaccinated 466. The experience in this epidemic was more favourable, 458 of the 1,832 vaccinated subjects escaped attack, as compared with 8 of the 466 unvaccinated controls. The vaccine used in this trial was prepared from a freshly isolated strain of *H. pertussis*. In the second trial, as in the first, the disease was less severe and the deaths proportionately fewer among the vaccinated than among the unvaccinated. Taking both epidemics together, the mortality among the vaccinated was 0·15 per cent., as compared with 2·4 per cent. among the unvaccinated. These trials suggested that prophylactic immunization with an *H. pertussis* vaccine is only moderately effective in preventing the disease, but is of very real value in decreasing severity and mortality.

Extensive trials have been carried out by numerous workers in the United States and Canada (see Sauer 1933*a*, *b*, *c*, 1935, Kendrick and Eldering 1936, Siegel and Goldberger 1937, Doull *et al.* 1939, Rambar *et al.* 1941, Bell 1941, Daughtry-Denmark 1942, Perkins *et al.* 1942). With the exception of the series recorded by Doull and his colleagues, the results were uniformly favourable. Success has also been reported by Oláh (1942) in Hungary and by Dungal, Thoroddsen and Ágústsson (1944) in Iceland.

Before accepting these findings, it is necessary to point out that in some of the observations recorded there was no control group, and that in others the method of selecting the controls was not above criticism. In mass immunization experiments too much care cannot be taken to ensure that the treated and the control subjects are as similar as possible in every respect. The fallacy of offering immunization to a given group of subjects, inoculating those who accept and treating the remainder as controls, has already been pointed out in relation to B.C.G. vaccination (p. 1339). It is particularly difficult in clinic practice to be sure that children in the two groups are exposed to equal risks of infection. The most reliable method, therefore, is to inoculate alternate children in a residential nursery or similar institution, in which all the children are mixed together and in which infection, if it is introduced, will spread to all alike. A small investigation made under these conditions by McFarlan and Topley (1943) in a residential nursery in Berkshire revealed no difference in either the incidence or the severity of the disease between the vaccinated and the control groups. A similar completely negative result was obtained by McFarlan, Topley and Fisher (1945) in a carefully controlled trial in clinics and day nurseries at Oxford.

What is the explanation of these discrepancies? Several factors have to be considered, such as the mode of preparation of the vaccine, the size, number and spacing of the doses, and perhaps most important of all the perfect equalization in every respect of the groups of inoculated and control children. This is not the place to enter into a critical analysis of these factors; suffice it to say that they differed in practically every one of the trials referred to. We feel therefore

that, though strong presumptive evidence has been brought forward by American workers for the value of inoculation in the prophylaxis of whooping cough, the case is still far from proven. Further trials under more stringent conditions must be carried out before the efficacy of this method can be accepted, and before it is introduced as a routine measure into child welfare practice.

Serum Treatment.—Since 50 per cent. of deaths from whooping cough occur before the age of one, and since the formation of antibodies during the first few months of life is poorer than it is later (see Baumgartner 1933–34, 1937), it is clear that, even if a satisfactory vaccine was available, it would be of little help in the protection of very young infants. For these a therapeutic serum is required. Mention has already been made in Chapter 33 of the separation of a toxin from *H. pertussis*. Evans (1940) has shown that by the injection of toxin into rabbits an antitoxic serum can be produced, capable of neutralizing the necrotic effect of toxin introduced into the skin. How far such a serum is likely to be of value in human beings is at present doubtful. Bullowa and his colleagues (1942) found that antitoxic serum prepared in rabbits had no therapeutic activity in children, but if given prophylactically early in the incubation period of the disease, it appeared to protect a high proportion of them against whooping cough. Strean (1944), on the other hand, has claimed valuable therapeutic activity for the serum (see also Strean, Lapointe and Dechene 1941). Further work will obviously be required to establish the value of serum in the prevention and cure of whooping cough. It may be added that the sulphonamide drugs have already proved their worth in the treatment of secondary broncho-pneumonia, which is so often responsible for a fatal outcome in infants and young children.

Secondary Broncho-Pneumonia

Influenza, whooping cough, measles, and to a less extent certain other specific infective diseases, are peculiarly liable to be associated with a secondary infection of the lungs ; and it is this fact which is answerable for the high mortality associated with such diseases. The case mortality during an epidemic of influenza, for instance, is almost entirely determined by the frequency of pulmonary complications. Without entering into the pathology of these pulmonary lesions we may note that the distribution is usually of the broncho-pneumonic type ; and that the pneumonias associated with influenza are frequently characterized by certain features, which serve to distinguish them from those which follow measles or whooping cough. Thus, in cases of influenzal pneumonia, the lesions of the bronchi are often unusually severe ; hæmorrhages into the alveoli, into the bronchi, or around the bronchioles, are frequently encountered ; and localized areas of necrosis, or suppuration, are not uncommon (see Opie *et al.* 1921).

The bacteriology of secondary broncho-pneumonia in general, and of influenzal pneumonia in particular, differs from that of primary lobar pneumonia in the fact that the pneumococcus plays a far less predominant rôle ; and that, among the pneumococcal cases, the commoner " infective " serological types (see next section) are found to be responsible for only a small minority of the infections. In influenzal pneumonia, *H. influenzæ* may play a dominant rôle. Hæmolytic streptococci, which play a negligible rôle in primary lobar pneumonia, frequently invade the lung during an influenzal attack, and give rise to a particularly fatal type of infection. In whooping cough it is probable that *H. pertussis* itself plays a large, but not an exclusive, part in the production of lung lesions.

The species of bacteria isolated from the sputum, blood, or empyema fluid during life, and from the lungs or other tissues at autopsy, vary from place to place and from time to time. There is definite evidence, in the records, of a secondary local prevalence of a particular bacterial species, imposed on the primary prevalence of influenza, or of measles; so that one observer may record a high incidence of streptococcal pneumonia, another a considerable series of secondary pneumococcal infections, and a third may note the occurrence of numerous pulmonary infections due to *Staph. aureus* (see for example Smith 1935, Finland, Peterson and Strauss 1942). Among the less frequent infective agents we may note *Bact. friedländeri*, capable of producing an acute, suppurative and usually fatal pneumonia (see Solomon, 1937, 1940, Hyde and Hyde 1943) and streptococci of the *Str. viridans* type (Solomon and Kalkstein 1943, Thomas 1943). The figures recorded by Dwinell (1919), in 69 autopsies on fatal cases of influenzal pneumonia, may be regarded as typical of an outbreak in which hæmolytic streptococci are playing a predominant part. The frequency of the various bacterial species in this series of cases was as follows.

		Per cent.
Hæmolytic streptococci	41 cases	= 59·4
Pneumococcus (all types)	8 „	= 11·6
Non-hæmolytic streptococci	17 „	= 24·6
Staphylococci	13 „	= 18·9
H. influenzæ	34 „	= 49·3

The predominance of pneumococcal types other than I, II, and III in any outbreak of influenzal pneumonia in which *Str. pneumoniæ* is the principal secondary agent is illustrated by the following figures, giving the type of pneumococcus isolated from 105 cases of influenzal pneumonia (Opie *et al.* 1921).

	Per cent.
Type I	7·6
Type II	21·9
Type III	5·7
Other Types	64·8

In many infections by the organisms mentioned in this section, the disease may, on both clinical and pathological grounds, be classified as a primary pneumonia. In others, the distinction between primary and secondary pneumonia is hard to make and, from many points of view, may not be worth making. Nevertheless, the term "secondary pneumonia" at least serves to remind us of the patient's predisposition to bacterial respiratory infections in diseases like measles and influenza; and from the foregoing it is clear that pneumococci, influenza bacilli, hæmolytic streptococci and staphylococci are the chief offenders in taking advantage of this predisposition, together accounting for the great majority of fatal infections.

The fact that these secondary pneumonic infections play a large part in determining the case-mortality rate in any outbreak of influenza, measles or whooping cough, raises a point of the first importance in regard to the effective control of these diseases. It is probable that the secondary bacterial invader responsible for the fatal issue is in many cases leading a vegetative existence in the upper part of the respiratory tract of the host, at the time when the primary infection is contracted. In other cases the host may receive the secondary invader

from the same source, and at the same time, as the primary infecting agent. There is, however, little doubt that a considerable proportion of fatal secondary infections result from the implantation, on a case of primary influenza or measles, of a virulent streptococcus or pneumococcus; and the records contain instances of waves of secondary infection, due to a particular bacterial species, passing through hospital wards, or concentration camps (see Opie *et al.* 1921). The conditions which, in the aggregate, make up the environmental factor known as "hospitalization," play the same part in secondary respiratory disease, as they play in the case of surgical or puerperal sepsis. The patient with influenza or measles should be regarded as peculiarly liable to acute respiratory infection, and should be carefully guarded from secondary infection. There is, for instance, ample evidence that overcrowding in hospital wards, or in military camps, may seriously increase the mortality during an outbreak of influenza or of measles (see Memorandum 1944).

There seems little hope that any form of prophylactic immunization, apart from immunization against the primary disease, will reduce the liability to such secondary infections. As will be obvious, we are faced with a multiplicity of heterogeneous bacterial antigens, and it seems scarcely reasonable to expect that we can ever induce immunity to all the bacterial species and types, to which a person with some primary predisposing infection may become a prey. The same heterogeneity of infecting agents severely limits the opportunities for the use of specific serum therapy.

Both the sulphonamides and penicillin are reported to be effective in the control of broncho-pneumonia due to staphylococci and streptococci. The sulphonamides are less effective against *H. influenzæ* and *Bact. friedländeri*, though some success is claimed for them.

Primary Pneumococcal Pneumonia

We need not here consider the clinical or pathological aspects of pneumonia as it occurs in man, nor discuss the vexed question of the classification of acute inflammatory lesions of the lungs. Excluding the broncho-pneumonias of young children, and the secondary pneumonias to which we have already referred, there remain a group of cases in which a severe pyrexial illness, with sudden onset and a tendency towards recovery by crisis in non-fatal cases, is associated with signs and symptoms of pulmonary involvement; and in which bacteræmia is frequently present during the initial phase of infection, and is a constant feature in severe and fatal cases. Infections of this type are, with very few exceptions, caused by the pneumococcus; and it is with such primary pneumococcal pneumonias that we are here concerned.

The Experimental Disease.—We have referred, in some detail, to the experimental study of pneumococcal infections in laboratory animals, when discussing the general problems of infection and resistance; and we may at this point confine our attention to certain experimental evidence which directly concerns the mechanism of pneumonic infection in man.

Blake and Cecil (1920*a*, *b*, *c*, Cecil and Blake 1920*a*, *b*, *c*, *d*) found that lobar pneumonia could consistently be produced in monkeys by inoculating minute amounts of pneumococcal cultures directly into the trachea. The disease so produced resembled lobar pneumonia in man: in its clinical manifestations; in its tendency to terminate by crisis; in the presence of a bacteræmic phase, which was transitory in cases that recovered, but progressive in cases that succumbed; and in the lesions found at necropsy in fatal

cases. Inoculation, by swabbing, of the nose and throat, never resulted in pneumonic infection. Monkeys which were inoculated intravenously, or subcutaneously, either died of pneumococcal septicæmia, without pulmonary lesions, or recovered without any involvement of the lungs. Blake and Cecil conclude that the normal route of infection in lobar pneumonia is *via* the bronchi, the disease spreading centrifugally through the interstitial tissues from the hilar region, and invading the alveoli from without. A similar mode of spread was postulated in rabbits by Permer (1923) and in mice by Branch and Stillman (1924). As the result of a study of human infections, an alternative view was put forward by Loeschcke (1931); the original focus of infection appeared to be near the periphery of the lung, and the infecting pneumococci seemed to be carried in œdema fluid from one alveolus to another, passing directly through the pores of Kohn. Subsequent experimental work on a number of animals has confirmed Loeschcke's view.

In dogs, pneumonia may be initiated by introducing pneumococci, together with viscous material like starch or mucin, into a terminal bronchus. The œdema fluid from the lesions, laden with pneumococci, passes directly through the alveoli and precedes the advancing consolidation. The greater the œdema in the initial lesion, the greater is the likelihood of spread; and not only are the site and spread of the lesions determined to some extent by gravity—the infected fluid tending to flow downwards—but they can be altered by appropriate changes in the posture of the sick dog (Terrell, Robertson and Coggeshall 1933, Robertson 1938, Hamburger and Robertson 1940, Robertson and Hamburger 1940). Loosli (1942) obtained similar results in monkeys, but concluded that in these animals the infection also spread from bronchiole to bronchiole as the result of repeated aspiration during breathing. In rats also the lesion advances by direct spread from alveolus to alveolus (Gunn and Nungester 1936, Wood 1941). The infected œdema fluid appears to outstrip the cellular response. At the edge of the pneumonic lesion one finds fluid and pneumococci only; then comes a zone containing active polymorphonuclear phagocytes as well; and not till the central region of consolidation is reached are active macrophages demonstrable. Since this central region may be bacteriologically sterile, it would appear that the macrophages not only ingest but kill the pneumococci.

It should be noted that the action of the starch or mucin in these experiments is not to block the bronchi and thereby induce collapse and subsequent infection in the tributary alveoli, but to protect the cocci against the defence mechanisms of the body (see Chapter 54). According to Hamburger and Robertson (1940) mere blocking of a bronchus does not predispose the corresponding alveolar portion of the lung to infection. It is probable that natural infections are initiated by the aspiration of pneumococci and mucinous material from the upper respiratory tract. Nungester and his colleagues, for example, have shown in rats that the *nasal* instillation of pneumococci and mucin does not result in pneumonia, but if by chilling or alcohol intoxication the normal mechanisms preventing the inhalation of fluids into the lung is deranged, pneumonia follows (Nungester and Klepser 1938). When mucin and pneumococci were introduced into the nose or the trachea, artificially imposed forceful inspiration induced pneumonia in about 50 per cent. of the rats tested. Forceful expiration, on the other hand, which in some respects is analogous to natural expulsive coughing, had a smaller predisposing action, for when it was imposed on the breathing of mice inoculated intratracheally, the incidence of pneumonia was only 18 per cent. (Nungester, Klepser and Kempf 1942).

As noted elsewhere, Gaskell (1927) carried out a large series of intratracheal inoculations in rabbits, and brought evidence to show that the type of infection produced in these animals is mainly determined by the virulence of the strain of pneumococcus injected, ranging, as virulence decreases, from a rapidly fatal septicæmia without pulmonary changes, through lobar and lobular pneumonia, and through lesions confined almost entirely to the bronchi and bronchioles, to a complete absence of reaction. The frequency with which pneumonia follows intranasal inoculation in mice has been found to vary both with the virulence of the strain and with the susceptibility of the animal used (see Rake 1936).

Though consideration of the epidemiology of pneumonia in man points overwhelmingly to the respiratory route of entry, the possibility of a blood-borne infection of the lung must be borne in mind. In this connection we may note that Rake (1936) by carefully balancing the virulence of the pneumococci against the resistance of the test mice induced pneumonia by intravenous inoculation; while Kempf and Nungester (1940) showed that pneumonia followed intravenous inoculation in rats previously given mucin intrabronchially.

If we collate the available experimental evidence with the numerous observations which have been carried out on the natural disease as it occurs in man (Dochez 1912, Sia, Robertson and Woo 1928, Finland and Sutcliff 1931*a*), we can construct a picture of the sequence of events in lobar pneumonia, which, however incomplete it may be, will aid us in the discussion of the results obtained in serum treatment, and in prophylactic vaccination.

It would appear that the initial phase of the infection is marked by a progressive invasion of the lung tissue, frequently associated with a detectable bacteræmia. The inflammatory reaction in the lung progresses through its successive stages; and the bacteræmia may, or may not, increase in severity. At some time between the 4th and 7th days, in favourable cases, specific antibodies begin to appear in the blood; and, coincidently with their appearance, the temperature falls by crisis, the pneumococci disappear from the blood if they were ever present in detectable numbers, and the clinical condition of the patient undergoes a striking amelioration, though abnormal signs in the lungs may persist for several days, or even weeks.

There are good grounds for believing that the degree and persistence of bacteræmia, rather than the local condition in the lungs, is the main factor in determining death or recovery. The most virulent of Gaskell's strains produced in rabbits rapid septicæmic death without pneumonic consolidation. In acutely fatal cases of pneumonia in man the lung changes at autopsy may be relatively slight; but blood cultures taken during life are, in such cases, almost always positive. The prognostic significance of a positive blood culture is one of the best-attested facts which have emerged from the bacteriological study of this disease.

Thus in a series of 448 cases, studied at the Hospital of the Rockefeller Institute, 136 gave positive blood cultures, and of these 76 died, a mortality of 55·8 per cent.; 312 gave negative blood cultures, and of these 26 died, a mortality of 8·3 per cent. (Avery *et al.* 1917). Tilghman and Finland (1937) examined a series of 1,586 cases due to all types of pneumococcus, and found that the fatality rate in bacteræmic patients was four times that in non-bacteræmic patients (see also Anderson *et al.* 1943).

In such series as these the figures given for positive or negative blood cultures must not be taken as an accurate index of the presence or absence of bacteræmia, but rather of its severity. The precise amount of blood withdrawn and, to a less extent, the method employed in cultivation will make a significant difference in the proportion of negative and positive results; and different observers have, in fact, recorded very different figures. But any one technique, employed over a considerable series of cases, will place in the positive category those patients who are suffering from a bacteræmia in excess of some limiting range, and in the negative category those whose blood is infected, less heavily, or not at all.

The Frequency of the Different Serological Types of Pneumococci in Health and Disease.—The antigenic structure of the pneumococci has been described in Chapter 24, where it is noted that the studies of Cooper and her colleagues (Cooper, Edwards and Rosenstein 1929, Cooper *et al.* 1932, Cooper and Walter 1935) resulted in the sub-division of the old "Group IV," composed of undifferentiated strains

into 29 new types; so that the differentiated and labelled types of pneumococci now run from Type I to Type XXXII, the classical Types I, II and III retaining their priority. The later work on the serological definition of strains not included in Cooper's types does not concern us here, for the present epidemiological and immunological data at our disposal relate almost entirely to Types I to XXXII. We may note that there is a close antigenic relationship between Cooper's Types VI and XXVI and between Types XV and XXX (Walter *et al.* 1940), and, as in Table 159, it is sufficient for our purposes to include Type XXVI in Type VI, and Type XXX in Type XV.

The earlier workers, distinguishing only Types I, II and III, and "Group IV" pneumococci, noted a number of characteristics in the distribution of pneumococci. In the first place, certain types predominated in infected persons, others in the nose and throat of healthy carriers. Avery, Chickering, Cole and Dochez (1917) found that in New York, during the few years prior to 1917, 80 per cent. of all cases of lobar pneumonia in adults were due to infection by Types I, II and III.

TABLE 158

FREQUENCY OF THE DIFFERENT SEROLOGICAL TYPES OF PNEUMOCOCCI IN LOBAR PNEUMONIA, AS RECORDED BY VARIOUS OBSERVERS.

Observers.	Country or District.	Period.	No. of Cases examined.	Frequency percentage.			
				Type I.	Type II.	Type III.	Group IV.
Schorer, Clark and others	U.S.A.	1917–18	101	30·7	14·9	17·8	36·6
Thomas	U.S.A.	1917–21	239	25·1	10·9	14·6	49·4
Cecil, Baldwin and Larsen	U.S.A.	1921–26	1,913	33·6	19·1	13·3	33·3
Griffith	England	1920–22	150	30·6	32·7	6·7	30·0
Glynn, Digby and Jones .	England (Liverpool)	1919–21	96	45·8	24·0	2·1	28·1
Ferguson and Lovell . .	England (Manchester)	1925–27	116	43·1	4·3	0·0	52·6

The percentage frequencies were Type I, 33·3; Type II, 33·5; and Type III, 13·0. In normal mouths, on the other hand, the percentage frequencies were Type I, 0·8; Type II, 18·2; Type III, 28·1. Group IV strains, which were associated with only 20·3 per cent. of pneumonias, were found in 52·9 per cent. of normal throats. Secondly, the incidence of the types varied from place to place, and from year to year in any one place. In Table 158 we summarize figures collected by Glynn, Digby and Jones (1923) from the literature with the addition of some collected at a later date. Cecil, Baldwin and Larsen (1927), during a 5-years' study of the distribution of the three types, noted that the frequency of Type I ranged from 21·0 per cent. to 45·2 per cent., that of Type II from 15·9 per cent. to 20·6 per cent., that of Type III from 7·9 per cent. to 17·2 per cent. and that of "Group IV" from 23·5 per cent. to 41·0 per cent.

In his study of lobar pneumonia among the mine-workers on the Rand, Lister (1917) carried out a serological analysis of 148 strains, 143 of which he allocated to 11 groups, labelled by letters, leaving 5 unclassified. The three major groups, A, B, and C, accounted for 31·0 per cent., 16·2 per cent., and 21·6 per cent. of the strains respectively, leaving

31·2 per cent. in the minor groups. Subsequent investigations have shown that Lister's Group C is identical with the American Type I, and his Group B with the American Type II; but his Group A, which was the type most frequently isolated in South Africa prior to 1916, together with a number of his infrequently occurring types, corresponded to the American "Group IV." Identities were subsequently established between most of the South African groups and Cooper's types, and Group A, for example, proved to be identical with Type V (see Ordman 1938).

In the third place, a marked difference was noted between the case-fatality rates of primary pneumococcal pneumonia according to the various infecting types. Type III infections showed a high fatality rate in the region of 40 per cent.; and the rates were progressively less with Type II, Type I and Group IV infections, in that order (see Glynn, Digby and Jones 1923, Cecil 1928, Rosenblüth 1928, Ferguson and Lovell 1928).

Since the differentiation of most of the Group IV strains into Cooper's types, many detailed surveys of pneumococci in health and disease have been made which have to a large extent confirmed the observations made on Types I, II and III alone, and which have revealed a number of additional features in the epidemiology of pneumococcal infection. We can do no more than indicate some of the outstanding results of these surveys; for details, the reviews of Finland (1942*a*, *b*) should be consulted.

All the newer types, IV–XXXII, have been found, with varying frequency, in association with respiratory infections. Types IV, V, VII and VIII are, after Types I, II, III, the most frequent types in acute lobar pneumonia of adults. In pneumonia of children and infants, the frequency of the types is different. Type XIV predominates; and Types I, VI and XIX, V, IV, III and VII are, in that order, next in frequency (see also Viktoroff *et al.* 1937).

We have recorded in Table 159 representative figures from Finland (1942*b*), showing the frequency of the Cooper types in pneumonia of adults and of children gathered from several American sources, and for healthy carriers surveyed in Germany by Gundel (1933) and in England by Straker and others (1939). The case-fatality rates are also listed for pneumonia in adults, and it will be seen that relatively high rates are recorded for infections with some of the newer types. As Finland points out, these rates do not fairly represent the capacity of the various types to produce a primary pneumonia in persons of average resistance, since many of the cases are of atypical, post-operative or otherwise traumatic pneumonia, in which the resistance of the patient has probably been substantially lowered by other causes.

With infections by all types, it has been found that the case-mortality rates are higher for atypical and secondary pneumonias than for acute lobar pneumonia; and since about three-quarters of the former are due to infection with the more recently described types (Stoneburner and Finland 1941) the high mortality rates may be due to host factors independent of the virulence of the types. If we take the occurrence of bacteræmia as an index of virulence, it is clear that of the new types, only Types IV, V, VIII, XIV and XXV approach Types I, II and III in this respect. Table 159 also shows that the type distribution in the pneumonias of children is conspicuously different from that in the pneumonias of adults. The distribution also varies within this group, according to the age of the child. Thus Nemir, Andrews and Vinograd (1936) found Type I in 7·7 per cent. and Type XIV in 36·0 per cent. of pneumonias in children under 2 years, whereas the corresponding figures in the 2–13-year-age group were 23·9 per cent. and 9·7 per cent. respectively. In healthy carriers the frequency is again different, Types III, VI, XVIII and types other than I–XXXII being commonest. The type-distribution in broncho-pneumonic infections at all ages, it should be noted, is similar to that in healthy carriers (see Finland 1937).

TABLE 159

INCIDENCE OF PNEUMOCOCCAL TYPES IN HEALTH AND DISEASE (after Finland).

Pneumococcus Type.	Pneumonia of Adults.						Pneumonia of Infants and Children		Healthy Carriers.	
	All Cases.				Bacteræmic Cases					
	Number of Cases.	Percentage of Total.	Died.	Percentage Mortality.	Number	Percentage of Type.	Number.	Percentage of Total.	Number	Percentage of Total.

XXIV	62	0·5	12	19·4	6	9·7	18	0·7	18	0·5
XXV	114	0·9	21	18·3	26	22·8	8	0·3	25	0·7
XXVII	26	0·2	3	11·5	2	7·7	1	0·1	17	0·5
XXVIII	46	0·4	14	30·4	2	4·3	18	0·7	60	1·7
XXIX	107	0·9	25	23·4	6	5·6	31	1·2	105	2·9
XXXI	32	0·3	9	28·1	2	6·3	17	0·7	22	0·6
XXXII	22	0·2	0	....	1	4·5	4	0·2	8	0·2
Not I–XXXII	49	0·4	11	22·4	3	6·1	12	0·5	593	16·7
	12,049	100·0	2,762	22·9	2,516	20·9	2,506	100·0	3,543	100·0

We must emphasize that these figures represent only limited surveys, and that frequencies vary with time, season, locality (see, for example, Rumreich *et al.* 1943), with prevailing epidemics, and the state of immunity of the population concerned, as well as with the methods used for the isolation and typing of the pneumococci. Nevertheless, within the limits of these variations, the type-frequencies reported from various parts of the world (see Mulder 1938, Ordman 1938, Bjørnsson 1940, Lal and Chitkara 1941, Stobo and Little 1941, Siegenbeek van Heukelom and Beeuwkes 1942) bear out the general conclusions that can be drawn from Table 159.

We can divide pneumococci into the relatively virulent or " infective " types, and the apparently less virulent, characteristically " carrier " types. The infective

types are commonly associated with acute pneumococcal pneumonia, and the carrier types are commonly found in the healthy human throat. This arbitrary division is not clear cut; as Table 159 shows, "carrier" types may cause severe pneumonia, and "infective" types are carried by healthy persons.

Carrier types are established in the throat in early life (see Sutliff and Davies 1937) and are found there at all ages. Carriage of any one type may persist for years (Straker *et al.* 1939), though the type may be detected only intermittently. Several types may be carried by one person; up to seven have been recorded. In a healthy community pneumococci may be found in 40 to 50 per cent. of persons sampled once; and in nearly all persons if the sampling is repeated at intervals over a long period (see Straker *et al.* 1939, Smillie, Calderone and Onslow 1943).

The similarity of the type-frequencies in broncho-pneumonia, and in post-operative and other kinds of traumatic pneumonia, to those in healthy carriers, suggests that these infections have their source in the upper respiratory tract of the patient himself; they may, in fact, be examples of autogenous infection. The virulence of the carrier type in these circumstances is usually attributed to a non-specific reduction in the resistance of the person attacked, though the factors predisposing to infection, such as the trauma due to an anæsthetic, are not in all cases apparent. In some cases, the age factor is important; Type VI, for example, is largely a carrier type in adults, and an infective type in infants and children.

As regards the infective types, though it is possible that a persistent carrier may succumb to infection with his own type, there are many examples of epidemic outbreaks in which the responsible pneumococcus apparently infects from without; that is, in which acute lobar pneumonia spreads by contagion. When we study the carrier rates for the infective types we find, in accord with the notion of their relatively high virulence, that high rates are associated with outbreaks of pneumonia. Thus in institutional outbreaks of Type I pneumonia, Type I carrier rates of 10 and 30 per cent. have been recorded (Stillman 1916, Strøm 1932). Dauer and others (1941) observed that in a group of 50 boys, five of whom had a Type II pneumonia, the healthy carrier rate for Type II was 44 per cent. It is clear that "infective" types can spread through a community. Indeed Andrews (1937), in a survey of pneumonia of infants due to a wide variety of types, found that the types associated with the highest incidence of pneumonia in infected persons, and with the highest case fatality, were also most frequently isolated from the throats of family contacts.

The relation of the carrier state and prevalence of pneumonia is well illustrated in Smillie and Jewett's (1940) survey of familial outbreaks of pneumonia. They found that, whereas the carrier rate for carrier types like XIX or XXVII was similar for contacts and non-contacts of Type I and Type II pneumonias, the Type I carrier rate in Type I contacts was 10 per cent., but only 0·8 per cent. in non-contacts; in Type II outbreaks the corresponding Type II carrier rates were 7·4 per cent. and 0·3 per cent. (see also Rogers *et al.* 1941, 1943).

It is noteworthy that high carrier rates are often found simultaneously with outbreaks of pneumonia, and that, as in some recent surveys, a high carrier rate for a given type may even precede an outbreak (Stebbins *et al.* 1940; see also Smillie and Jewett 1942). The evidence from a number of outbreaks, in fact, suggests that acute lobar pneumonia is but one manifestation of the spread of a virulent pneumococcus, presumably from a healthy carrier of the organism; other observed manifestations are the healthy carrier state, infection of the upper respiratory tract, conjunctivitis, otitis media, and mild atypical pneumonia (see Gilman and Anderson 1938, Plummer and Ensworth 1941). The concentration of carriers, as in infections by other bacteria, to some extent determines the appearance of manifest disease. Thus, in the school outbreak recorded by Dauer and others (1941) pneumonia appeared in the group of boys with a 44 per cent. carrier rate, but not in groups with lesser rates (see also Mackenzie *et al.* 1940). This relation, however,

is by no means found consistently. Stebbins and his colleagues (1940), for example, record an epidemic prevalence of a Type V pneumonia in the absence of a continued high carrier rate, and in another population a high carrier rate of Type VI without the appearance of Type VI pneumonia.

The available evidence, then, indicates that acute lobar pneumonia is a contagious disease, which is spread by carriers and by persons with a variety of pneumococcal infections of the respiratory tract, including acute lobar pneumonia itself. We have little precise knowledge of the circumstances that determine infection of the lung in a given person. Certain types of pneumococcus appear to infect more readily than others. As regards the part played by immunity of the host, we have noted some factors, like age, which are associated with resistance to various types of pneumococci. The rôle of specific immunity we shall consider in later sections of this chapter.

The Treatment of Pneumonia with Antipneumococcal Serum.

The sera employed in the treatment of pneumonia are prepared by injecting horses with whole cultures of pneumococci of one or more of the different serological types. All the laboratory evidence suggests that anti-pneumococcal immunity is type-specific; and we should not therefore expect a serum prepared against any one type to exert a curative effect on an infection caused by any other. Many of the early trials in man were, in fact, carried out with a " polyvalent " serum prepared by immunizing horses against Types I, II and III. It will be convenient to consider the results obtained in trials with this, and other, sera before discussing the question of how such antisera should be standardized and utilized.

We have quoted numerous experiments that establish the protective action of a type-specific antiserum as tested in the rabbit or mouse, and a few that indicate a curative action when the serum is injected shortly after the establishment of an experimental bacteræmia. In either case it has been shown that the serum increases the efficacy of the normal clearing mechanism and suppresses, or cuts short, the bacteræmic phase.

Of particular interest, from our present point of view, are the following observations. Cecil and Blake (1920*e*) studied the effect of serum treatment on experimental lobar pneumonia in monkeys, induced by the intratracheal inoculation of virulent Type I pneumococci. They found that the intravenous injection of the specific antiserum exerted a prompt therapeutic effect, freeing the circulating blood from pneumococci, shortening the infection and greatly reducing its severity. Of 5 treated monkeys all recovered while the controls died. Curphey and Baruch (1932) infected rabbits by the intradermal injection of virulent Type I pneumococci, and studied the effect of the subsequent injection of a Type I antipneumococcal serum by the intravenous or intramuscular route. With the intravenous injection of 400 units 24 hours after infection, 1 of 13 animals survived; with 800 units 12 of 32 animals survived; with 2,500 units 14 of 19 animals survived. With shorter intervals between infection and the administration of serum smaller doses sufficed to ensure the survival of a considerable proportion of the animals.

This method of treatment has since 1915 received an extensive clinical trial in man, particularly in America. It was, however, some years before its value was established with an approach to certainty, and a serious attempt was made to assess its effect in terms of a percentage reduction in mortality. Even now we can offer only approximate estimates, and some few observations are hard to fit into the general picture. The history of the serum treatment of pneumonia

affords an illuminating example of the neglect of a useful therapeutic measure that may follow a failure to plan early trials in such a way as to allow significant but undramatic effects to be measured with some approach to accuracy.

The earliest considerable series of cases are those recorded by Avery and his colleagues (Avery *et al.* 1917). In 107 cases of serum-treated pneumonia there were 8 deaths, a mortality of 7·5 per cent. There were no controls; but a favourable conclusion with regard to the influence of serum on mortality was based on the contrast between the observed case-fatality rate and the rates of 25–30 per cent. recorded by these workers before they commenced the use of serum, and by other observers elsewhere. This method of comparison is, however, not valid. The variability of the case-mortality rates in different outbreaks of pneumonia is well known; and the records of serum-treated cases show a similar variability, though, for the most part, over a smaller range. Thus Wadsworth (1924), commenting on a series of collected figures, notes case-fatality rates in serum-treated patients varying from 6·0 to 18·0 per cent. Clearly the only satisfactory way of assessing the effect of serum is to compare treated with untreated cases in the same place and at the same time. A considerable series of trials have been carried out along these lines. Concentrated polyvalent antipneumococcal sera containing antibodies for Types I, II and III have been used, the Type III antibody being present in relatively low concentration.

In a series recorded by Cecil (1928) the data were collected as follows. During the winters of 1920, 1921 and 1922 all cases of pneumonia admitted to six medical wards were treated with Huntoon's polyvalent antibody solution, while all cases of pneumonia admitted to six other wards were treated on ordinary medical lines without serum therapy. The results are recorded in Table 160.

TABLE 160

COMPARISON OF CASE-FATALITY RATES IN TREATED AND UNTREATED CASES OF LOBAR PNEUMONIA (CECIL).

Type of Pneumococcus.	Antibody Wards.			Control Wards.			Difference.	Diff./S.E. Diff.
	Cases.	Deaths.	Deaths Percentage.	Cases.	Deaths.	Deaths Percentage.		
I	158	21	13·3	162	36	22·2	8·9 ± 4·27	2·09
II	83	23	27·7	67	27	40·3	12·6 ± 7·74	1·63
III	73	29	39·7	60	24	40·0	0·3 ± 8·5	—
Group IV . .	110	18	16·4	121	29	24·0	7·6 ± 5·2	1·46

There is a clear suggestion that Type I and Type II pneumonias were benefited by the serum, while Type III pneumonias were not. Only in the case of Type I pneumonia does the difference between the treated and untreated groups as compared with its standard error attain a value that would be conventionally regarded as statistically significant. The suggestion that some therapeutic effect was exerted on pneumonias due to infection with strains belonging to the antigenically heterogeneous Group IV is not in accord with our expectations; but the difference in this case falls short of statistical significance.

A very valuable record is that provided by Park, Bullowa and Rosenblüth (1928). The serum employed was Felton's concentrated polyvalent antipneumococcal serum, and random sampling was ensured, as far as possible, by giving serum to alternate cases in order of admission. The relevant figures are set out in Table 161.

TABLE 161

Type.	Hospital.	Treated.		Untreated.		Difference Percentage.	Diff./S.E. Diff.
		Cases.	Deaths Percentage.	Cases.	Deaths Percentage.		
I	[1] Combined	266	19	249	33	14 ± 3·8	3·7
	Bellevue	144	19	132	33	14 ± 5·3	2·6
	Harlem	114	20	109	34	14 ± 5·8	2·4
II . . .	Combined	176	35	165	45	10 ± 5·3	1·9

	Bellevue	131	30	128	40	10 ± 5·2	1·9
	Harlem	171	20	190	15	− 5 ± 4·0	1·2

[1] The combined figures include a small series of cases treated at the New York Hospital.

Taking the combined experience it will be noted that the concentrated serum exerted a significantly beneficial effect on Type I pneumonia. In Type II pneumonia the effect is more doubtful. The combined experience clearly suggests a beneficial effect; but this is due almost entirely to the results obtained in Bellevue Hospital. In Harlem Hospital over the same period of time serum-treated Type II pneumonias showed no advantage, a fact that emphasizes the danger of putting trust in small numbers or in single trials. The Type III cases received no benefit from the serum. The Group IV cases were unaffected as judged by the combined experience. In Bellevue they seemed to receive some benefit. In Harlem they fared worse than the controls. We need not then attach much importance to the apparent therapeutic effect in Group IV cases noted by Cecil.

Cecil and Plummer (1930) record a series of Type I pneumonias treated with Felton's serum between 1924 and 1929. Of 239 treated cases 20·1 per cent. died; of 234 untreated cases 31·2 per cent. died, giving a difference of 11·1 ± 4·01 per cent. With Type II pneumonia the results were curious (Cecil and Plummer 1932); of 252 treated patients 40·5 per cent. died; and of 253 untreated patients 45·8 per cent. died. But analysing the results season by season, the differences in case mortality were 15·0 per cent., 7·3 per cent., and 15·1 per cent. in favour of the treated, and then 7·5 per cent. and 4·8 per cent. in favour of the untreated cases. In a subsequent season 1930–31 the trial was continued on the alternate case method, limiting the treated and control groups to cases of Type II pneumonia admitted within 72 hours of onset. Of 21 treated cases 3 died; of 20 control cases 13 died (see also Cecil 1937).

The therapeutic value of Types I and II antisera depends to some extent on the age of the patient treated. It has been found, for example, that whereas the case mortality in the 20–40 age group is significantly lower in treated than in untreated cases, there is little difference in the 40–60 age group (Report 1934; see also Langley *et al.* 1937).

Horse antisera against Types IV, V, VII, VIII and XIV pneumococci have also been tested in the United States in controlled series of cases: the results indicate that serum treatment reduces the mortality due to Type V and VII pneumonia by about half (see Bullowa 1937, Finland and Brown 1939*a*, Benjamin *et al.* 1937, Kohl and Reitzel 1936). The antisera to Types IV, VIII and XIV were also reported to have a favourable effect, though the evidence was for various reasons less clear cut.

More recently, therapeutic rabbit antisera, as developed by Horsfall and his colleagues (1937), have largely replaced horse antisera in the United States. Antisera can be prepared more quickly in the rabbit, in some cases (e.g. Types II and VIII) with higher titres of protective antibodies than are usually obtained in the horse; and, after a refining process which removes substances that give rise to thermal reactions, they can be used safely in man. The rabbit antibody globulin particle is less than one-quarter the size of the horse antipneumococcal antibody, and thus possesses the theoretical advantage of being more likely to diffuse readily through the infected tissues of the patient (see Chapters 7 and 47). Rabbit antisera to Types I, II, V and VII have proved to be at least as effective as the corresponding horse antisera; and there are indications that antisera to Types III, IV, VIII and XIV have a beneficial effect. Antisera to all the remaining Cooper types have been tested, but in most cases the results are inconclusive, partly owing to the small number of patients so far treated, and partly to the complicating factor of sulphonamide treatment. Comparisons of case-mortality rates, however, suggest that specific serum is most effective in infections with Types XII, XX, XXV and XXVI; less so with Types IX, X, XVII, XVIII, XXIV; and fairly effective with Types VI, XIX, XXII, XXIII, XXIX and XXXII (Finland 1942*b*; see also Madsen and Vammen 1940).

The results of clinical trials are in entire accord with the view, based on laboratory experience, that the therapeutic effect of each of these sera is type-specific, depending in the main on the content of the antibody acting on the capsular, type-specific, polysaccharide antigen.

If, then, we intend to use an antipneumococcal serum we must determine the type of infecting pneumococcus at the earliest possible moment.

The method of typing usually employed is to inject a specimen of sputum into the peritoneum of a mouse, to kill the animal after 6 to 8 hours, and to carry out agglutination and precipitation tests with the sediment and supernatant fluid of the peritoneal washings. This method can be made more rapid by using slide agglutination followed by staining (Sabin 1929), and noting the swelling of the capsule that results from the action of the antiserum, as well as the agglutination itself. This capsular-swelling reaction, which was first described by Neufeld (1902), can be applied to specimens of sputum direct (see Armstrong 1932, Logan and Smeall 1932, Sabin 1933 Beckler and MacLeod 1934, Cooper and Walter 1935, Bullowa 1935, Mulder 1935, Vinograd, Nemir and Park 1936, Cruickshank and Montgomery 1938). In experienced hands, the agreement of the results of typing by the direct swelling reaction and the indirect after mouse-inoculation varies between 75 and 90 per cent.

Type-specific polysaccharides, detected by precipitin tests with specific antisera, are found in the urine of patients with pneumonia (Dochez and Avery 1917). In the early stages of the disease, positive reactions are too infrequent to be depended upon as an indication of the infecting pneumococcal type (Cruickshank 1938, Cruickshank and Montgomery 1938).

As regards the dose of serum and the number and frequency of the injections that should be administered, there are good reasons for believing that these factors are of primary importance. We might suppose from our knowledge of passive protection in the rabbit or mouse that a comparatively small dose of serum would suffice to render the pneumococci sensitive to phagocytosis. But the experiments of Curphey and Baruch (1932) show that, with antibacterial as with antitoxic sera, the effective curative dose is a high multiple of the protective dose. It is probable that this is in part due to the fact that the specific antigen, or hapten, accumulates in the lesions and in the blood in considerable quantities during a pneumococcal infection and exerts an aggressive effect, combining with the corresponding antibody and so diverting it from the living pneumococci.

Thus, Park and Cooper (1928) note that, when an antipneumococcal serum is injected into a normal person, the specific antibody disappears relatively slowly from the circulating blood; so that one-quarter to one-half of the amount administered is still present 24 hours after an intravenous injection. In severe cases of pneumonia the course of events is quite different; the specific antibody is rapidly neutralized. If a polyvalent serum is administered it will be found that the antibodies corresponding to types other than that responsible for the infection can be detected in the circulating blood for relatively long periods, as in normal persons (see also Langley *et al.* 1936).

By suitable titration in cases of Type II pneumonia, Park and Cooper were able to show that the circulating antigen alone would require several thousand units of antibody for its neutralization. In Chapter 48, we noted the enormous amounts of specific polysaccharides estimated to be present in the pneumonic lungs, particularly in Type III infections, amounts that for their full neutralization would require litres of concentrated antibody; and though it is unlikely that all the antigen held in the tissues must be neutralized before any injected antibody is available for direct action on the invading pneumococci, the aggressive action of a substantial part of it will necessarily affect the outcome of serum therapy.

In this connection, it should be noted that Cruickshank and Montgomery (1938) demonstrated that the presence of urinary, and, therefore, presumably of circulating, polysaccharide in the early stages of pneumonia was of bad prognostic significance. The death rate in 62 such patients was 38·7 per cent., whereas, of 53 patients whose urine was persistently free, only 1 died.

Park and Cooper recommend that every pneumonia patient should, on admission to hospital, receive 10,000 units of Type I and Type II antibody administered intravenously. So long as the temperature remains high, the injections should be continued every 8 to 12 hours. When the type of the infecting pneumococcus has been determined a monovalent serum may be substituted for the polyvalent preparation. If the infection is found to be due to a type of pneumococcus against which no specific serum is available, the injections should be discontinued (see also Bullowa 1937).

The Standardization of Antipneumococcal Sera.

In the original attempts to measure the potency of such a serum (see Neufeld and Händel 1909, Neufeld and Schnitzer 1927–28) titrations were made in mice both with a constant dose of serum and a varying dose of pneumococci, and with a constant dose of pneumococci and a varying dose of serum.

These and later experiments (see Felton 1930*a*) have made it clear that the relation between the number of pneumococci injected and the dose of serum necessary to protect against them is not of a simple linear kind, *i.e.*, if x ml. of serum will protect against y pneumococci it does not follow that nx ml. of serum will protect against ny pneumococci. Felton's experiments suggested that, under optimal conditions, this linear relationship held over a limited range; but the results obtained by Smith (1932) indicate that it is very unsafe to assume that if one serum in a particular dose gives a certain degree of protection against n pneumococci, and another serum in the same dose gives the same degree of protection against $2n$ pneumococci, the second serum is twice as potent as the first. He found, for instance, that with a constant dose of a particular serum and varying doses of pneumococci, the death rate in a group of 50 mice receiving 12,500 cocci was greater than that in another group of 50 mice receiving 125,000 pneumococci, while in another experiment a hundredfold increase in the number of pneumococci, keeping the dose of serum constant, failed to cause any significant increase in the percentage mortality.

It happened, however, for reasons that are not altogether clear, that the method of varying the dose of pneumococci was at first adopted in testing antipneumococcal sera

(see Prausnitz 1929). Sera were not titrated in terms of units, but a limit of potency was laid down which had to be attained before a serum was regarded as satisfactory for issue. In Germany this limit was protection by 0·2 ml. of serum against 0·1 ml. of a culture of such virulence that 0·000,001 ml. was fatal for untreated mice. In America it was protection by 0·2 ml. of serum against 0·1 ml. of a culture of such virulence that 0·000,000,1 ml. was fatal for untreated mice. A method that does not assign a value in terms of units to each batch of serum issued is clearly unsatisfactory from the clinical point of view, and of more recent years attempts have been made to improve the method of standardization, though no international agreement has yet been reached.

Felton (1925, 1928, 1930*a*, *b*, 1931) has carried out extensive studies on this problem, adopting the method of testing varying doses of the serum to be standardized against a constant dose of pneumococci and defining the unit of serum as the least amount that will protect mice against 1,000,000 lethal doses of a virulent pneumococcal culture. His studies, and those of Parish (1930), Trevan (1930), Falk *et al.* (1931) and Smith (1932), make it clear that the unit value of a serum cannot be accurately determined by direct titration against any particular pneumococcal culture. Smith, for instance, in repeated titrations of a particular serum against a particular strain of pneumococcus found that the amount of serum necessary to protect 50 per cent of mice against the test dose of culture employed varied between 0·0009 ml. and 0·0034 ml. Felton (1930*a*) would ascribe such divergent results, particularly when different strains of pneumococci are employed, to independent variation of virulence and of capacity to unite with antibody.

This difficulty may in any case be avoided by comparing an unknown serum with a standard serum, and assigning a value to the former, not in terms of the particular dose of pneumococci against which it protects, but in terms of the arbitrary unit value assigned to the standard preparation. Any variation in the culture will presumably affect the neutralizing power of the standard and the unknown serum to the same extent; and it is probably a fair assumption that, if n ml. of the standard and $2n$ ml. of the unknown serum each give a mortality of 50 per cent. when injected into an adequate sample of mice together with the same dose of the same pneumococcal culture, the unknown serum contains half as many units of protective antibody as the standard.

The titration curves recorded by Parish (1930), Trevan (1930) and Smith (1932) make it clear that this method allows an assay within a reasonable degree of accuracy provided that an adequate sample of mice is injected with each dose. Actually the standardization of an antipneumococcal serum to within a margin of error of $\pm$ 30 per cent. demands the use of 40 mice for each dose of the unknown serum tested, and another 40 mice for each dose of the standard serum with which it is to be compared.

It may be added that the common practice is to inject the serum and culture simultaneously into the peritoneum and to use 0·0025–0·1 ml. of culture as the test dose, according to its virulence and bacterial content. The virulence should be maximal, so that 10 pneumococci or less will kill untreated mice, and the inoculum should correspond to 500,000–5,000,000 lethal doses.

An important saving in mice would obviously be effected if we could substitute an *in vitro* for an *in vivo* test. The type-specificity of the protective action clearly suggests that the effective antibody is that which corresponds to the type-specific polysaccharide; but, equally clearly, we must establish this identity by direct experiment before we can accept an *in vitro* estimation of this antibody as affording an adequate measure of protective value.

Certain of the earlier observers (see for instance Wadsworth 1917) reported a complete and puzzling lack of correlation between agglutinin titre and protective power.

It seems likely that some particularly unfavourable conditions must have affected such results as these; since Falk *et al.* (1931) and Felton (1931) record a close parallelism between agglutinin titre and protective power in mice. Felton, testing 39 sera by both methods, reports a correlation coefficient of + 0·80; but his protocols show a few markedly divergent results.

Since the isolation of the type-specific polysaccharide hapten of Heidelberger and Avery (1923) attempts have naturally been made to correlate precipitin content with protective power, and these have, on the whole, given better correlation than the agglutinin estimations (see Sobotka and Friedlander 1928, Friedlander *et al.* 1928, Zozaya *et al.* 1930, Heidelberger *et al.* 1930, Falk *et al.* 1931, and Felton 1931). Few of these comparative titrations can, however, be regarded as an adequate test, since the method of optimal proportions was not followed in determining the precipitin content of the serum.

Smith (1932), using the optimal-proportion method of Dean and Webb (1926) in the precipitin estimations, and injecting adequate samples of mice (40 for each dose of serum) in the protection tests, compared several Type I antipneumococcal sera with a particular serum taken as a standard. With unconcentrated sera, the correspondence between precipitin and protective antibody content was good. With concentrated sera, however, the protective power was greater than that indicated by the precipitin content (see also Hartley *et al.* 1933, Smith *et al.* 1934, Goodner and Horsfall 1937). The use of selected antigenic fractions of the pneumococci in precipitin tests for the standardization of sera has many advantages over the laborious and expensive mouse-protection tests, and may eventually replace them. But it must be emphasized that the establishment of the identity of the antibody to the specific polysaccharide and protective antibody is but a first step in the transition to *in vitro* tests. The antigenic preparation used must be constant in composition and serological reactivity; the lability of the acetyl group in the Type I polysaccharide (see p. 280) provides an example of the difficulties to be expected. Moreover, as we saw in Chapter 7, the antibodies in native antisera are often heterogeneous. In a given antibody fraction, protective and precipitating powers may be widely discrepant; and even where we find a dependable parallelism of the two in native antisera, it may, as suggested by the results of Smith's experiments (see also Lyall 1941), be disturbed during their concentration and refinement for therapeutic purposes.

Chemotherapy of Acute Lobar Pneumonia.—Since the demonstration of its efficacy in acute lobar pneumonia by Evans and Gaisford (1938) sulphapyridine has been successfully used in the treatment of all kinds of pneumococcal infections, including acute lobar pneumonia (see, for example, Ordman 1939, Ormiston *et al.* 1942, Anderson 1943).

Sulphadiazine and sulphathiazole appear to be equally effective (see Spink 1942); and sulphamezathine (see Melton 1944) and sulphapyrazine (Ruegsegger *et al.* 1943) have been reported on very favourably. Penicillin is likewise said to be of value (Tillett *et al.* 1944). The relative efficacy, ease of administration, independence of the infecting type of pneumococcus, and cheapness of the sulphonamides, has tended to a replacement of serum therapy by chemotherapy. As we have seen in Chapter 54, there is every reason to believe that different processes are concerned in the antibacterial action of sulphonamides and of specific antibody. We might, therefore, on *a priori* grounds expect that the two together would be more effective than either alone. Finland and Brown (1939*b*), for example, demonstrated a synergic effect of the two in combination on the bactericidal power of human blood. Wright and Gunn (1940), on the other hand, in a test of experimental Type III pneumonia in rats, found sulphapyridine to be more effective than serum, and the combination of serum and drug to be no better than sulphapyridine alone. Clinically there are few reports that indicate a marked synergic effect. Finland (1942*b*) has reviewed the results of a number of clinical trials in America. In a general summary of infections by all the Cooper types, the mortality was 30·5 per cent. in 2,473 untreated

cases, 14·9 per cent. in 9,053 serum-treated cases, 7·6 per cent. in 12,547 sulphonamide-treated cases and 13·4 per cent. in 12,167 patients receiving combined therapy. For individual types, the figures were more variable, serum treatment being more successful than sulphonamides in infections with the less common Cooper types. The case mortality in the group receiving combined therapy was almost double that in the group receiving sulphonamide alone; but this does not necessarily mean that serum had a deleterious effect, for, as Finland points out, it is probable that serum treatment is combined with sulphonamides mainly in patients whose illness, by reason of its severity or other prejudicial factors, is not responding to the drug; therefore a higher mortality is in any event to be expected in this group (see also Shackman and Bullowa 1943). But aside from case-mortality rates, there is clinical evidence of an early crisis and of other improvement induced by type-specific serum, which suggest that serum therapy is a useful adjuvant to chemotherapy, especially in patients with bacteræmia.

It has been shown that drug-fast pneumococci are sometimes produced by sulphonamide therapy of experimentally infected animals (Chapter 54). The induction in man of pneumococci sufficiently drug-fast to be a danger to the patient himself, or to persons who become infected with the drug-fast strain, appears to be a rare event (Grumbach and Hegglin 1942, Hamburger *et al.* 1943) though Frisch, Price and Myers (1943) record cross-infection of a patient with a sulphadiazine-fast Type VIII pneumococcus. It is not possible to judge the magnitude of the problem until further evidence is forthcoming.

Other Possible Methods of Specific Treatment.

In view of the relatively poor therapeutic powers of Type III antipneumococcal sera, and the relative frequency of this type of infection, it is perhaps worth noting an alternative method of treating this type of infection; though, so far as we are aware, no trials in man have yet been made (see Cecil *et al.* 1936). This method depends on an observation made by Dubos and Avery (1931). These workers isolated a bacterium which, when grown in a synthetic medium containing the specific polysaccharide of Type III pneumococcus as the source of carbon, elaborates an enzyme that specifically attacks this hapten. The enzyme has no bactericidal action on Type III pneumococci, but it attacks the polysaccharide hapten as it is produced by the growing bacterial cells. When mice are injected with the specific enzyme together with a fatal dose of virulent Type III pneumococci they are effectively protected (Avery and Dubos 1931); and the protection is sharply type-specific. The enzyme also exerts a curative action in mice if injected during the earlier stages of infection. Goodner, Dubos and Avery (1932) studied the curative action of this enzyme on Type III infections in the rabbit, induced by the intradermal injection of a virulent strain. This type of infection, which starts as a spreading local lesion and leads, in untreated controls, to an acute bacteræmia fatal on about the 3rd or 4th day, offers obvious advantages for studies of this kind as compared with the acutely fatal peritoneal infection in the mouse. The enzyme, injected intravenously in adequate dosage 24 hours after the intradermal injection of pneumococci, was found to have a striking curative effect. In one series of tests, for instance, one of 19 treated animals died as compared with 36 of 38 untreated controls. Goodner and Dubos (1932) studied the relation between the degree of bacteræmia 24 hours after infection and the curative dose of enzyme given at this time. Of 10 rabbits showing 3–10 pneumococci per ml. of blood and receiving 2·5–100 " units " of enzyme all survived. Of 11 rabbits showing 103–630 cocci per ml. of blood, 5 that received 4–10 units died, 6 that received 20–100 units recovered. Of 9 rabbits showing over 13,000 cocci per ml. of blood and receiving 5–100 units of enzyme all died. Francis, Terrell, Dubos and Avery (1934) record a series of observations on the curative effect of this enzyme on experimental Type III pneumonia in the monkey. In 68 untreated monkeys the mortality was 50 per cent.; in 40 treated monkeys it was 20 per cent. (see also Dubos 1932, 1935, Dubos and Bauer 1935).

Prophylactic Immunization against Pneumonia.

The records of antipneumococcal immunization in laboratory animals are copious, and their significance is unequivocal. It is clear that susceptible animals, such as mice and rabbits, can be immunized with almost uniform success against infection by the usual routes. More immediately pertinent, perhaps, are the observations of Cecil and Blake (1920*a*, *b*, *c*) and Cecil and Steffen (1923, 1925), which showed that monkeys could be immunized with a considerable measure of success against intratracheal infection with Type I or Type II pneumococci, though the results with Type III were less promising (see also Chapter 50).

As in serum treatment, however, all the evidence suggests that the immunity acquired is predominantly type-specific ; and it is clear that, with so heterogeneous a species as the pneumococcus, this factor will seriously limit the usefulness of mass immunization. It is possible that vaccination against a few prevalent types might produce a significant decrease in the incidence of the disease, even though it failed to eliminate it, or to reduce it to negligible proportions ; but this we can only tell by experience.

The records of field trials on man tell a rather puzzling story. The frequency of lobar pneumonia, though very high in the aggregate, is not concentrated on particular age groups or confined in considerable part, as are diphtheria and scarlet fever, to schools and institutions. There are, however, certain environments that entail a particularly high risk of infection ; and, in some of them, trials have been carried out on a considerable scale.

The most extensive data are those provided by the report of Lister (1917) on the result of vaccination against pneumonia among the native labourers on the Rand mines. The numbers at risk were large ; but over the greater part of the period of trial the natives were not divided into inoculated and uninoculated groups. An earlier trial (see Orenstein 1931), in which 55,900 natives of various tribes had been divided into two equal groups, one inoculated and the other uninoculated, had shown a pneumonia incidence of 16·4 per 1,000 among the inoculated, 20·6 per 1,000 among the controls. As a result, wholesale inoculation was commenced in many mines, and the only basis of comparison available is that between the incidence of pneumonia in a particular mine before and after the institution of active immunization. As we have seen, this method of comparison is liable to many errors. There was, in fact, a definite fall in the incidence of pneumonia following these mass inoculations ; but the pneumonia death rate on the Rand had fallen sharply from the high level of 1907–11 before mass immunization was instituted, and there is no need to assume that the fall in death rate from 1916–20 was other than a continuation of the trend that was already well marked over the period 1911–14. Orenstein (1931) would attribute the whole downward trend to circumstances other than immunization, in particular to the decrease in the recruitment of tropical natives since 1911. If, as seems probable, we can attach little significance to the secular change in incidence or mortality we are left with ancillary evidence concerning the prevalence of particular infecting types in the pre- and post-inoculation periods. Lister had previously classified the strains of pneumococci isolated from the Rand miners into a series of types, of which A, B and C accounted for more than 70 per cent. of cases. Subsequent investigations have shown that Lister's Types A, B and C correspond to the classical Types V, II and I. Lister at first gave three subcutaneous injections consisting of 2×10^9 cocci of each type. In a particular trial 82 cases of pneumonia occurred among some 10,000 inoculated natives ; but none of these were due to infection with Type A, B or C. The subsequent history of events on the Rand is, however, very difficult to interpret. In 1917 a change was made in the constitution of the vaccine, each dose containing 1,000,000,000 cocci of each of eight different types

(see Ordman 1931). The pneumonia death rate continued to fall till about 1920–22, and then rose; the rise, though not great, was most marked in the last 3 years of the period under review—1927, 1928 and 1929. Orenstein (1931) notes that, in 1929, inoculation was discontinued in certain mines. The mines in which inoculation was continued had a higher attack rate in 1930 than in 1928, while the mines in which inoculation had been stopped had a lower attack rate. It may be, as Ordman (1931) has suggested, that the more recent failure in immunization was due to a change in the type of infection, not only in the prevalent types of pneumococci but in the rôle played by other bacterial species. In so far as this is the case, it illustrates the difficulty of immunizing against the clinical syndrome "pneumonia," which after all is the practical problem to be faced.

Environmental conditions particularly favourable to the occurrence of lobar pneumonia were provided in some of the camps and depôts during the war of 1914–18. Cecil (1925) reviews the results of a considerable series of mass inoculations carried out in America during the period 1918–19. As in so many of the medical records of the war, military exigencies often prevented the fulfilment of the conditions needed for a satisfactory statistical comparison. At Camp Upton, among 12,519 vaccinated men no case of pneumonia due to Type I, II or III pneumococci occurred during the trial period, while 26 cases occurred among 20,000 unvaccinated controls; but the incidence in the controls was very low, and the significance of the difference is rendered doubtful by the fact that pneumonias due to other types of pneumococci, and streptococcal pneumonia, were also more frequent among the controls than among the inoculated, a result that can hardly be attributed to the inoculation. At another depôt 38 cases of pneumonia were recorded among 48,849 vaccinated men, an incidence of 83·5 per 100,000; and 83 cases among 49,463 unvaccinated men, an incidence of 168 per 100,000. The types of infecting pneumococci in this series are not specified.

A third large-scale trial has been recorded by Malone (1925) and by King (1925). This was carried out on Indian troops in the Baluchistan district. The vaccine employed contained Type I and Type II pneumococci, 2,500,000,000 of each, and two injections were given. Among 2,996 inoculated men the pneumonia incidence was 9·346 per 1,000; among 5,227 uninoculated controls it was 10·714 per 1,000, a quite insignificant difference. The lack of protection could not be ascribed to a difference in the incidence of the different pneumococcal types among the inoculated and uninoculated; analysis of the type-frequencies showed that there was no significant evidence of protection against Types I and II.

The results of immunization with specific polysaccharide are on the whole as equivocal as those with vaccines. The studies of Felton and his colleagues in America show clearly that Type I and Type II polysaccharides may be as effective as a vaccine of whole bacilli in stimulating the production of protective antibodies in man, though individual responses are highly variable (Felton 1938, Felton, Cameron and Prather 1941, Felton *et al.* 1941). A field test, involving several thousand men in both control and inoculated groups, was made in two winter camps. In one, during an average period of observation of 10 weeks, the incidence of pneumonia in the uninoculated was 15·69 per 1,000 man-years of exposure to the prevailing infections, and 1·73 per 1,000 man-years in the inoculated; in the other, over an average period of observation of 17 weeks the corresponding rates were 7·28 in the uninoculated, 4·34 in the inoculated. The camps differed in many respects, but it is possible that the smaller effect of immunization in the second camp was the result of the longer period of observation; if so, it indicates that the protective effect of the inoculation is of relatively short duration. There was some evidence of protection against heterologous as well as homologous types (Ekwurzel *et al.* 1938). Siegel and Muckenfuss (1941), working under different epidemiological conditions, observed a community of feeble-minded persons for four years, and could find no evidence that the incidence of pneumonia, whether due to homologous or heterologous types, was affected by immunization with a mixture of Types I and II, and later Type III, polysaccharides.

It may be added that in a number of institutional epidemics due to a known type

of pneumococcus, immunization of the population at risk by type-specific vaccines or polysaccharides has been followed by marked diminution or cessation of the outbreak (Bonne 1936, Smillie 1936, Smillie, Warnock and White 1938, Dauer *et al.* 1941). However, the natural and sometimes sudden decline of an epidemic, especially in closed communities, is so common a phenomenon that the value of the vaccines in these cases cannot be assessed with any confidence.

In summary, it would seem fair to conclude that there is presumptive evidence, based on animal experiments, that immunization with particular types of pneumococci will afford some increase in resistance to infection with these types. This evidence has not been strengthened by the results of recorded trials in man; and it would seem that, with our present methods, the increase in resistance attained is either slight or transient. It may be, as Felton and Prather (1939) suggest, that the small proportion of persons who react feebly to a pneumococcal antigen are naturally more liable than the good reactors to infection with that type of pneumococcus; so that unless feeble reactors are selected for intensive immunization, the community as a whole may not benefit from immunization. Good reactors presumably respond rapidly to infection by an epidemic type of pneumococcus, and become carriers. The fact that, in a number of small outbreaks, a high proportion of the contact-carriers have been found to develop type-specific protective antibodies (see Finland, Brown and Barnes 1940, Plummer and Ensworth 1941, Rogers *et al.* 1943) is in accord with this view.

It is possible that chemoprophylaxis will prove more effective than vaccination in conferring protection on specially exposed or susceptible populations; but though a number of claims for the value of this method have been made, no one of the large-scale trials of sulphonamide on which they are based has been carried out under such conditions as to carry complete conviction.

Skin Reactions in Pneumonia.

We may close this section by noting certain observations which, though not immediately applicable to the practical control of the disease, have considerable theoretical significance.

Tillett and Francis (1929) tested the effect of intradermal injections of purified pneumococcal polysaccharide, and of pneumococcal protein, into patients suffering from pneumonia. They found that convalescent patients reacted to the injection of the polysaccharide by developing a wheal-and-erythema reaction which appeared within 30–60 minutes and then rapidly faded. This reaction was type-specific. Injection of pneumococcal protein, on the other hand, produced a delayed erythematous reaction reaching its height in 18–24 hours. This reaction was not type-specific. Finland and Sutliff (1931*a*, *b*) confirmed these observations, noting that the wheal-and-erythema reaction appears at or about the time of the crisis in patients who recover, while it is usually absent in cases that end fatally. In certain groups of subjects in whom repeated tests were carried out, they found that skin-sensitivity to the later injections appeared to develop as the result of the earlier ones. They also observed (Finland and Sutliff 1931*a*) that skin sensitivity was induced by the intravenous administration of an anti-pneumococcal serum. Francis (1933) records an extended experience of the occurrence of the immediate wheal-and-erythema reaction in 53 cases of Type I pneumonia, 48 of which were treated with Type I antipneumococcal serum. The results confirmed his previous finding that the appearance of the reaction has a favourable prognostic significance, and that its absence is suggestive of a fatal issue. The appearance of the reaction is correlated with the presence of specific antibodies in the blood, in the sense that the skin reaction is never present if antibodies are absent; but the skin test may

be negative though circulating antibodies are present, and its absence, even in such cases, seems to retain its bad prognostic significance. Finland and Dowling (1935) record a further study of the response to the intradermal injection of pneumococcal polysaccharide, in which they were able to show that the injection of purified polysaccharide, prepared by two different methods, induced characteristic skin sensitivity and, in addition, led to the appearance of specific antibodies in the serum. Subsequent work has not confirmed the high degree of correlation between the presence of antibody and the immediate skin reaction, particularly in naturally immune persons, though the correlation is better in specifically immunized persons (see Finland and Brown 1938, Felton and Prather 1939).

These observations are of interest in that they provide confirmation of the antigenicity of the polysaccharides in man, and indicate that a specific cell activity, associated with, but not entirely determined by, the presence of antibodies in the blood, is an important factor in the protective mechanisms of the tissues. Their significance is clearly not confined to the particular case of pneumonia.

Felton and Prather (1939) record that in man a *negative* reaction to an intradermal injection of a compound of specific polysaccharide with homologous antibody may be used to indicate the presence of antibody in the circulation. It remains to note that the presence in the serum of the " C-reactive " substance during the acute stage of pneumonia and other febrile diseases (see Chapter 49) is accompanied by a skin reactivity to the C-substance of the pneumococcal cell (Francis and Abernethy 1934).

Pneumonia in the Lower Animals due to *H. bronchisepticus*

In 1911 M'Gowan isolated *H. bronchisepticus* from the respiratory tract of a number of dogs, cats, rabbits and guinea-pigs. He regarded the organism as a primary cause of canine distemper—a view that has since been disproved (see Chapter 88). *H. bronchisepticus* is now known to be a frequent cause of infectious pneumonia in the lower animals, particularly in guinea-pigs (Smith 1913). It is present often in pure culture in the bronchi. Injected intraperitoneally into guinea-pigs in a dose of 0·5 ml. of a 24-hours' broth culture it causes death in 24 to 48 hours; post mortem there are small hæmorrhages on the peritoneum, and a viscid translucent exudate forming pseudomembranes on the liver, spleen, and the less mobile parts of the intestine; the bacilli are easily recovered from the peritoneal cavity, but with difficulty from the blood, liver or lungs. Subcutaneous injection produces a local lesion only; feeding and inhalation are without effect. The organism is non-pathogenic to mice. It rapidly loses its virulence in culture outside the body.

CHAPTER 75

UNDULANT FEVER, CONTAGIOUS ABORTION OF CATTLE, AND ALLIED INFECTIONS. TULARÆMIA

UNDULANT FEVER

Ever since the time of Hippocrates a low type of fever characterized by fairly regular remissions or intermissions has been recognized along the Mediterranean littoral. Several names have been applied to it, of which Malta fever and Mediterranean fever are the two best known. In 1887 Bruce reported the discovery of a small micro-organism, which he called *Micrococcus melitensis*, in the spleen of patients dying of the disease. Its injection into monkeys gave rise to a remittent fever, sometimes terminating fatally, and the organism was recovered in pure culture from the liver and spleen. Nearly 20 years later Zammit (1905) of the Malta Board of Health showed that the organism also infected goats. Further work rendered it evident that the goat was in fact the natural host of *Br. melitensis*, and that infection was carried to man by the consumption of raw milk.

In 1918 Evans drew attention to the similarity between the organism isolated from Malta fever and that described by Bang (1897) as the cause of a widespread disease in cattle known as contagious abortion. Her observations were soon confirmed, and in honour of Sir David Bruce the generic name *Brucella* was proposed for the two organisms. The close similarity between *Br. melitensis* and *Br. abortus* suggested the possibility that this latter organism might be pathogenic for human beings. It was not long before Bevan (1921–22) brought evidence to prove the correctness of this surmise. He drew attention to the occurrence in Southern Rhodesia of cases of undulant fever affecting persons who had apparently had no direct or indirect contact with goats. In the areas concerned epizootic abortion of cattle was prevalent, and it appeared probable that infection was being transferred to man by raw cow's milk. Numerous investigators turned their attention to this subject, and before long cases of undulant fever due to *Br. abortus* had been reported from practically every country in the world.

A third causal agent of this disease is *Brucella suis*—an organism originally described by Traum (1914) in the United States. Its natural habitat is the pig. Man becomes infected chiefly by contact with diseased carcasses, and undulant fever due to this organism has therefore a very definite occupational incidence.

These findings have necessitated a reconsideration of the nomenclature of the disease. Since all three organisms give rise to very much the same symptoms in man, and since *Brucella* infections are now known to be widespread over the globe, the term Malta fever is no longer generally applicable. It is being gradually replaced by the term undulant fever, which is free from any geographical connotation. Though this term is satisfactory for febrile infections, it is rather misleading

if used in reference to non-febrile infections with *Brucella* organisms, which are now being recognized as increasingly common. Hence the term Brucellosis has been suggested on analogy with tuberculosis, to apply to all types of *Brucella* infections, febrile or non-febrile, overt or latent, in animals or in man. This term has little to recommend it, since these considerations apply almost equally to diseases caused by other infective agents. We prefer ourselves to use instead the term " Brucella infection."

For the sake of clarity we propose to give a separate description of the epidemiology of undulant fever in man due to the three type organisms. We shall deal first with infections caused by *Br. melitensis*, including in our description the general symptomatology and bacteriology of the disease.

Undulant Fever due to Br. melitensis

Synonyms: Malta fever, Mediterranean fever, Neapolitan fever, Country fever of Constantinople, New fever of Crete, Rock fever of Gibraltar. French: *Mélitococcie.*

Quoting from the classical monograph of Hughes (1897): " Clinically, the fever has a peculiarly irregular temperature curve, consisting of intermittent waves or undulations of pyrexia, of a distinctly remittent character. These pyrexial waves or undulations last, as a rule, from 1 to 3 weeks, with an apyrexial interval, or period of temporary abatement of pyrexial intensity between, lasting for 2 or more days. . . . This pyrexia is usually accompanied by obstinate constipation, progressive anæmia, and debility. It is often complicated with, and followed by, neuralgic symptoms referred to the peripheral or central nervous system; arthritic effusions; painful inflammatory conditions of certain fibrous structures, of a localized nature; or swelling of the testicles." Numerous clinical types are recognized, such as the malignant, the undulatory, the intermittent, and the irregular type. In addition, there are subclinical infections, which can be diagnosed only by bacteriological methods, and infections that may remain latent for weeks or months before flaring up or retrogressing. For a description of these the reader is referred to Marston (1863), who first differentiated Malta fever from other fevers, to Hughes (1897), whose clinical study has never been improved upon, and more recently to Rainsford (1935) and Lisbonne and Janbon (1935). Several complications may occur, beyond those already mentioned, including osteomyelitis, which usually takes the form of localized bone abscesses, bronchitis, and acute inflammation of one or other of the visceral organs (see Michel-Béchet *et al.* 1939).

The commonest symptoms are probably asthenia, fever, muscular and articular pains, nocturnal sweats—often drenching—anorexia, constipation, nervous irritability, and chills or rigors (Taylor and Hazemann 1932).

The incubation period is variable. It may be as short as a week or as long as several months. Most commonly it is 10–30 days. The duration of the illness varies from a few days to over a year, 3 months being the usual time.

Bacteriology.

Bacteriologically, the work of Bruce (1887, 1888, 1893), of Hughes (1893, 1897), and of the Mediterranean Fever Commission (Report 1905–07) showed that the disease was a septicæmia. Working in Malta, Bruce (1893) was able on two occasions to grow the organism from the juice obtained by splenic puncture, and subse-

quent observers showed that, in the early stages of the disease, *Br. melitensis* could frequently be isolated from the peripheral blood. The post-mortem appearances agreed with this interpretation; there was an increase of pericardial fluid, congestion and enlargement of the liver, and great hypertrophy of the spleen. The presence of small areas of congestion in the mucosa and submucosa of the intestine, and the enlargement of the mesenteric glands, the interior of which often consisted of semi-purulent material, were suggestive of an alimentary mode of infection. Cultures taken post mortem from the spleen, liver, and lymphatic glands were positive in 100 per cent. of cases, from the kidney in 85 per cent., and from the heart blood, pericardial fluid and bone marrow in about 50 per cent. (Kennedy 1906). *Br. melitensis* was never found in the saliva nor in the sweat of patients, but it was shown to be quite commonly excreted in the urine. Kennedy (1905), who made a special study of this point, examined no fewer than 1,974 specimens of urine from 61 different patients. In 186 of the samples from 33 of the cases he obtained positive cultures. In a series of 43 cases, in which 20 or more samples from each patient were examined, the organism was isolated from 31. Often the organism could be detected for only 1 day; sometimes it was excreted daily for 2 or 3 weeks. From these figures it may be concluded that, at some time or another, probably at least 75 per cent. of patients suffering from Malta fever pass the specific agent in their urine; this excretion may be sudden and transitory, or it may last for weeks, extending onwards into convalescence.

As the organism is not infrequently found post mortem in the gall-bladder, it is reasonable to suppose that it must be excreted in the fæces. This is probably so, but the technical difficulties of isolating it are considerable. Eyre (1908), however, obtained a positive culture from the colon of a case which came to autopsy.

Outside the body, the organism was found to be fairly resistant; dried on cloth, it remained alive for 17 days, in dust for 44 days, and in sterile tap-water for 20 days (Kennedy 1905).

Epidemiology in Malta.—The epidemiology of undulant fever due to *Br. melitensis* varies in different countries. Since it has been studied most fully in Malta, we may review briefly the findings of the Mediterranean Fever Commission (Report 1905–07) in this island. The maximum incidence rate in Malta was found to occur in July and August. Generally speaking, it varied directly with the atmospheric temperature and inversely with the rainfall. The most susceptible age was between 11 and 30 years, but the disease occurred at any time of life. The upper classes of the civilian population and the officers of the services suffered more heavily than the lower classes and the non-commissioned ranks respectively. During the 33 years 1859–91 the incidence of the disease varied between 269·5 per 1,000 in 1859 and 91·2 per 1,000 in 1888. In spite of this comparatively high rate of morbidity, the mortality rate was low—about 2 per cent. But the duration of the fever and the prolonged disability following its actual termination combined to render it a potent cause of invalidity.

At the time of the Commission's appointment the mode of infection was still unknown. Several ways were suggested, but little evidence was produced in favour of any particular one. Johnstone (1905), who conducted an epidemiological inquiry into the disease, reported that neither food nor drink appeared to have any marked connection with the spread of the fever; nor did dust infection or direct personal contagion play a part. Similarly Davies (1906) concluded that

neither water, milk, nor any other articles of food seemed to be responsible in any way; he favoured a theory of contagion, either direct or through the agency of moquitoes.

It was left to Zammit of the Malta Board of Health, and a member of the Commission on Mediterranean Fever, to indicate the true path of infection. In his first communication (1905) he reported that 5 out of 6 goats which he had examined gave a positive agglutination reaction to *Br. melitensis*. From the blood of two of these animals, he succeeded in cultivating the actual organism itself. Horrocks (1905) rapidly confirmed this, and further demonstrated the frequent presence of *Br. melitensis* in the milk and the urine of apparently healthy goats. Kennedy (1905), who examined the blood serum of 161 goats from 8 different herds, demonstrated the presence of specific agglutinins in no fewer than 84 or 52·2 per cent. of specimens. This high incidence of infection was found to exist not only in the public herds, but in those animals that were kept privately under special care.

As it was evident that *goats' milk* was probably the main source of infection, it was desirable to ascertain on a large scale the proportion of infected animals. For this purpose, Zammit's test was found to be of great value. It consists in observing the presence of agglutinins, not in the blood serum, but in the milk of the goats. The proportion of infected goats judged by this test is definitely lower than that given by the serum agglutination test, since only 60–85 per cent. of the animals showing blood agglutinins also contain agglutinins in their milk. Zammit (1906) examined 710 samples of milk, and obtained 133 positive reactions. From every milk giving a strong reaction he was able to isolate *Br. melitensis* in culture. Horrocks and Kennedy (1906), who made numerous investigations both by the serum and by the milk agglutination test, came to the conclusion that 41 per cent. of the goats in Malta were infected, and that 10 per cent. of those that supplied milk were excreting *Br. melitensis*. It was found difficult to recognize the infected animals on clinical grounds; they did not suffer from a true fever, and though some showed loss of weight, a thinning of the coat, and a short hacking cough, others remained perfectly well and displayed no sign of illness. The amount of milk secreted was likewise no criterion, for the infected animals frequently yielded as much and more than the non-infected ones.

From these investigations it was apparent that the goats of Malta were heavily infected with *Br. melitensis*, and that about 10 per cent. of the milch goats were excreting this organism in their milk. As the majority of milk consumed in the island was goats' milk—cows are few owing to insufficient pasturage—it was easy to see how the disease might be transmitted to human beings.

Steps were taken by both the Navy and the Army, in 1906, to stop the supply of goats' milk to the troops. The result was most striking. Within a year the disease had been practically eradicated, only a few easily explained cases occurring. Amongst the civil population, such radical steps could not be taken; the gradually decreasing incidence observed during the following years was largely due to the killing off of many of the infected goats (Table 162).

This method, however, afforded no permanent protection, and the disease continued to exact a heavy toll. Of recent years it has been increasing in extent and severity among the civil population. There has, in fact, been a steady rise from 1926, when there were 596 cases with 27 deaths, till 1934, when there were 1,909 cases with 88 deaths.

TABLE 162 (taken from Eyre 1908, 1912).

	Civil.		Navy.		Army.	
	Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.
1901 . . .	642	54	252	3	253	9
1902 . . .	624	45	354	2	155	6
1903 . . .	589	48	339	6	404	9
1904 . . .	573	59	333	8	320	12
1905 . . .	663	88	270	7	643	16
1906 . . .	822	117	145	4	163	2
1907 . . .	714	78	12	0	9	1
1908 . . .	502	?	6	—	5	?
1909 . . .	456	?	10	—	1	?
1910 . . .	318	?	3	—	1	?

Consumption of goats' milk was not the only method of infection, though it was undoubtedly the most important for the troops and naval ratings on the island. Contamination of the skin or mucosæ with infective material—particularly common in laboratory workers—afforded another method. Occasionally infection appeared to be insect-borne, or transmitted by sexual congress (Eyre, McNaught, Kennedy, and Zammit 1907).

The history of Malta fever is instructive. In the first place, it affords an excellent example of a disease whose incidence was not immediately affected by the discovery of the causative agent. In order to prevent a disease, it is not necessary to know the causative agent, so long as we know the way in which it spreads. Once this is known, the steps necessary for limiting it may be considered. In some cases, as in that of milk-borne disease, the steps may be relatively simple ; stop the supply of milk, or insist on its adequate heat treatment, and the infection can no longer be transmitted to human beings. In other cases, notably the respiratory diseases, the problem is more difficult. No satisfactory method for preventing the inhalation of infected material has yet been devised ; and until this proves possible, measures against these diseases will be more profitably directed towards increasing the host resistance than to interfering with the spread of infection.

The second point of interest is that, in an epidemiological inquiry, it is harder to assess the importance of a given factor when it operates more or less uniformly throughout a population, than when it is distributed in such a way as to affect different sections unevenly. Both the epidemiologists who investigated the disease in Malta (Johnstone 1905, Davies 1906) reported that there was no evidence to suggest that infection was conveyed by food. Both of them overlooked the fact that a disease spread by an article of almost universal consumption, such as goats' milk, would show little preference for any one class of the population, if the contamination of the milk were widespread and frequent, rather than local and occasional. The clue to the problem was furnished by the bacteriologist. It was this second discovery, that a large proportion of goats contained agglutinins in their blood for *Br. melitensis*, which complemented the first discovery, that of the organism itself, and pointed out the way by which the spread of the disease might be checked.

(For an excellent account of the epidemiology of Malta fever in the Royal Navy, see Dudley 1931.)

Epidemiology in Other Countries.—The next most important bacteriological and epidemiological study of the disease has been made by Taylor and his colleagues in the South of *France*, working at the Undulant Fever Centre established at Montpellier by the Rockefeller Foundation (see Taylor and Hazemann 1932, Taylor, Lisbonne, and Roman 1932, Taylor, Lisbonne, and Vidal 1935, Taylor *et al.* 1938*a*). The disease was found to be widespread in the south-east of France, where sheep and goats are common and cattle are relatively few. The incidence in males was 2–3 times that in females, and was highest in the 15–45 age group. The occupational incidence was very striking, the majority of the cases occurring in the agricultural community, especially among those engaged in rearing sheep and goats. The seasonal prevalence was at its maximum in the spring, corresponding to the time of lambing and abortion. Though the consumption of goats' milk, and of fresh cheese made from goats' or ewes' milk, undoubtedly played some part in infection (see Carrieu and Lafenêtre 1932, Veloppé and Jaubert 1935), the evidence on the whole suggested that infection most frequently resulted from direct contact with infected animals and manure. In a population, however, living under very primitive conditions, and exposed to many sources of infection, it was difficult to ascertain with certainty which was the most important route by which the organisms gained access to the body. The very interesting observation was made (Taylor, Vidal and Roman 1934) that cows in close contact with sheep and goats might become infected with *Br. melitensis*, excrete this organism for months in the milk, and give rise to undulant fever in human beings consuming it in the raw condition.

The disease affects several other countries, including Italy, Spain, Greece, Transcaucasia, Algeria, Tunis, Palestine, Arabia, India, South Africa, China, and various parts of South America. Like Malta, Corsica and Sicily are seriously affected. In this country, owing to the absence of *melitensis* infection in sheep and goats, disease due to this organism does not occur. In the United States there is a certain amount of undulant fever due to *Br. melitensis* in the goat-raising areas, but most of it is due to *Br. abortus* and *Br. suis*.

Undulant Fever due to Br. abortus

In its general symptomatology and bacteriology this disease resembles that caused by *Br. melitensis*. Though, as will be pointed out later, the ability of *Br. abortus* to give rise to undulant fever is less than that of *Br. melitensis*, once the typical disease has developed, it seems to pursue its course more or less independently of the type of the causative organism. The incubation period is very variable, ranging from a week or so to 6 months or more (see Hardy, Frant and Kroll 1938). The average duration of the disease is 3 months, and the case mortality about 2 per cent. Besides typical cases, however, a considerable number of so-called subclinical infections occur, characterized by only slight pyrexia and by a variety of different symptoms. Evans (1934) draws attention to the frequency in these patients of exhaustion, insomnia, irritability, and subjective disturbances, leading to a diagnosis of neurasthenia. Sometimes there is an acute influenza-like illness lasting for not more than a week, while at others a low intermittent fever may persist for months or even years. Acute abdominal symptoms are not uncommon, and in several patients an appendicectomy or cholecystectomy has been performed before the real nature of the disease was recognized (Simpson 1930). Chronic infections may occur (see Evans *et al.* 1938, Calder 1939).

Infection during pregnancy is sometimes, but not often, followed by abortion. The organism may be isolated from the placenta and uterus of the mother and from the stomach contents of the fœtus (see Kristensen and Holm 1929, Spengler 1929, Simpson 1930, Alessandrini and Pacelli 1932, Habs 1933*a*, Lauda 1934, Menzani and de Zanche 1934).

Frequency.—Though the disease is widespread throughout the world, its frequency is difficult to assess. As in tuberculosis, the reported cases may bear very little relation to the real incidence of infection. The reason for this is partly that the disease is still unknown to many practitioners, partly that it is impossible to diagnose with certainty except by bacteriological methods, and partly that in several countries, including Great Britain, the disease is not reportable. The so-called reported cases often refer to mere collections by private persons. The nearest approach we can make to ascertaining the incidence of the disease is by indirect methods, particularly by noting the proportion of sera from patients with undiagnosed pyrexia which agglutinate *Br. abortus* to a significant titre. In some countries, such as Denmark, where serological examination of pyrexial patients is common, and where all sera are examined under standard conditions in one central laboratory, it is easy by this means to obtain a fair estimate of the frequency of active infection with *Br. abortus*. In other countries, such as our own, where serological examination, especially in rural areas, is more restricted, and where sera are examined in multiple scattered laboratories, collection and integration of the data are very much harder. With reservations to be made later for certain occupational classes which are exposed to frequent infection with *Br. abortus*, a titre of 1/80 or over in febrile patients can be regarded as probably indicative of active infection. Having ascertained the proportion of Widal sera agglutinating *Br. abortus*, the probable number of cases of infection can be calculated, either directly if the total number of Widal sera examined in the whole country is known, or indirectly by a method described elsewhere (Wilson 1932*a*). The results obtained (see Table 163) are essentially estimates, and probably err on the conservative side. (For references to figures used, see Kristensen and Holm 1929, Holl 1930, Weigmann 1931, Bijl and v.d. Hoeden 1931, Süpfle and Hofmann 1932, Bach 1932, Fried 1932, Grumbach and Grilichess 1932, Messer 1932, Dettling 1932, Wade 1933, Hall 1933, Russ 1934, Kalbfleisch and Kalbfleisch 1935.) It will be

TABLE 163

PROPORTION OF WIDAL SERA AGGLUTINATING *Br. abortus* TO 1/80 OR OVER, AND ESTIMATED ANNUAL NUMBER OF UNDULANT FEVER CASES ABOUT 1930.

(Data compiled from several papers in different countries; for references, see text.)

Country.	No. of Sera Examined.	No Positive.	Percentage Positive.	Estimated Annual Number of Undulant Fever Cases.	No. of Cases per 1,000,000 Population.
Great Britain . . .	3,175	101	3·18	440	11
Germany	9,397	323	3·44	600	10
Austria	9,693	177	1·83	50	8
Switzerland	1,503	91	6·1	340	84
Holland	4,500	50	1·11	90	12
Denmark	4,623	500	10·82	500	147
Sweden	—	—	—	120	20

seen that the incidence of the disease, calculated per million of the population, is much the same in Great Britain, Germany, Austria, Holland, and Sweden, but that it is considerably higher in Switzerland and Denmark. In the United States undulant fever is known to be very prevalent, but as some of the cases are due to infection with *Br. suis*, and the antigenic structure of this organism is closely related to that of *Br. abortus* (see Chapter 34), figures based on agglutination results are not strictly comparable with those just given. There is evidence to suggest that the different incidence in different countries is dependent to some extent on the frequency of contagious abortion in cattle, and the degree of exposure of the human population, though other factors undoubtedly play a part (Henricsson 1932, Olin 1935). Some of the difference is almost certainly more apparent than real, and is due to the much better diagnostic facilities available in certain countries than others. Further data on the incidence of the disease may be consulted for Great Britain (Menton 1937), Yugoslavia (Simitch and Djourichitch 1936), South Africa (Campbell and Greenfield 1937) and Canada (Dolman and Hudson 1938).

Latent Infections.—Besides definite clinical disease, *Br. abortus* gives rise to a considerable amount of latent infection. Examination of Wassermann sera in this country and in Germany shows that about 1·5 per cent. agglutinate *Br. abortus* to a titre of 1/40 or over. The titre is generally less than 1/160, and high titres, such as those yielded by the majority of sera from patients with undulant fever, are uncommon. A certain proportion of these sera are derived from patients actually suffering from the disease. The majority, however, come from persons with no clinical evidence of undulant fever. The probability is that these agglutinins are due to latent infections with *Br. abortus*. This interpretation is supported by two facts. The first is that agglutinins, even in a titre of 1/20, are rarely present in the sera of persons who do not drink raw milk or cream, and who are not exposed to contact with infected animals. The second is that agglutinins are present in quite a high proportion of persons who drink considerable quantities of infected raw milk or cream, or whose duties bring them into close contact with infected animals (Table 164). (For references to figures used, see Lentze 1930, Martin and Myers 1931, Maclean 1932, Wilson 1932*b*, Starr and Maxcy 1933, Molinelli, 1933, 1934, Hermann *et al.* 1934, v. Berkessy and Simon 1934, v. Berkessy 1935, Zimmermann 1935, Rossi 1935) (see also Beattie 1938).) The figures given in the table include the United States and the Argentine, in both of which countries there is some infection with *Br. suis*, but it will be seen that in all countries about 10–20 per cent. of persons in these special occupational classes contained agglutinins to *Brucella*. Investigation showed that some of these persons were suffering from undulant fever at the time of examination, or had recently recovered from it, but most of them had no symptoms indicative of active infection. An exception should perhaps be made for veterinary surgeons, several of whom suffered from an allergic condition, which manifested itself in the form of a rash on the arm developing after " cleansing," *i.e.*, evacuation of the cow's uterus (see Huddleson and Johnson 1930, Haxthausen and Thomsen 1931, Wilson 1932*b*, Thomsen 1937*c*).

The conclusion seems to be that infection with *Br. abortus* resembles in many respects infection with the tubercle bacillus. Both organisms have a fairly high degree of infectivity enabling them to establish themselves, at least temporarily, in the tissues. Neither of them, however, has a high pathogenicity, so that in the majority of persons the infection remains latent or retrogresses. Only in a small proportion of infected persons are the conditions favourable for the production

TABLE 164

PROPORTION OF SERA AGGLUTINATING *Br. abortus* TO 1/40 OR OVER IN PERSONS EXPOSED TO INFECTION.

of clinically detectable disease. It is probable that latent infections often lead to latent immunization, thus explaining why undulant fever does not occur more often than it apparently does in veterinarians. There is also evidence to suggest that persons who are exposed to heavy infection for the first time, or after a long interval of freedom from exposure, are more likely to develop the disease than those who are exposed to mild infection more or less continuously. Garrod (1937) has drawn attention to the susceptility of *Br. abortus* to the bactericidal action of the gastric juice, and suggests that this may be one reason why undulant fever is not commoner than it is. It would be idle to pretend, however, that we have any exact knowledge of the factors determining the course of infection in any given individual, and those who deny the pathogenicity of *Br. abortus* for man because not every exposed person develops the disease, must be wholly unaware of the complexity of the equilibrium existing between host and parasite. The possibility that strains of *Br. abortus* vary in virulence must be considered, but so far there is no evidence to support it (see Birch and Gilman 1935, Olin 1935).

Mode of Infection.—The mode of infection varies in different countries and in different parts of the same country. The main source is obviously cattle, and man becomes infected by consumption of raw milk or cream, or by contact with infected animals, either alive or dead. Generally speaking, the town population is exposed to infection from milk, while the country population is exposed to both milk-borne and direct contact infection.

Numerous records in different countries show that a considerable proportion of samples of raw milk coming from infected herds contain living *abortus* bacilli. In Great Britain about 20–30 per cent. of herd samples are infected. Experience has shown that *consumption of raw infected milk* is attended by a certain risk of contracting the disease, whereas consumption of the same milk after pasteurization or other effective heat treatment is harmless. In London, where about 98 per cent. of the milk is heat-treated, and in the large cities of the United States

where most of the milk is pasteurized, undulant fever is practically unknown. The cases that do occur are mostly among those who drink Certified or other types of raw milk, either at home or on a visit to the country.

Several careful studies made in institutions and small communities supplied with infected raw milk have shown that a considerable proportion of the population develop serum agglutinins, that a small proportion suffer from subclinical and clinical forms of undulant fever, while, in a larger proportion, the infection remains completely latent. Removal of the infected animals, or pasteurization of the milk supply, is followed by cessation of clinical illness and by a gradual disappearance of agglutinins from the sera of latently infected persons (see King and Caldwell 1929, Hasseltine and Knight 1931, Sasano, Caldwell and Medlar 1931, Dooley 1932, Johns, Campbell and Tennant 1932, Wilcox 1932, Carpenter and Boak 1933, Welch and Mickle 1933, Hall and Learmonth 1934, Cameron and Wells 1934, Stone and Bogen 1935, von Engel 1938, Elkington *et al.* 1940, Cruickshank and Stevenson 1942).

It may be pointed out here that alimentary infection is almost always due to the consumption of raw milk or cream. Butter and cheese, except when made from untreated milk and consumed within a week or two, are probably inoffensive, since the organisms die out very rapidly as the result of lactic fermentation (Mazé and Césari 1931, Caronna 1936, Taylor *et al.* 1938*a*). Moreover, a large proportion of manufactured butter is made from pasteurized cream in which the organisms are destroyed (see Smith, J., 1934*a*, Pullinger 1935). One curious laboratory outbreak, possibly associated with defective plumbing, is on record (Huddleson and Munger 1940).

Contact infections are mainly occupational, occurring in towns among slaughterers, and in the country among the farming population. Since the latter class, in particular, is usually exposed to infection from raw milk, the parts played by the two sources of infection are very difficult to determine. In countries with a large agricultural population, such as Denmark, it follows that the incidence of undulant fever is greater in rural than in urban districts, whereas in countries such as our own, where about 80 per cent. of the population is concentrated in towns, the reverse holds true. Contact infection is mainly from cattle, but horses and even dogs may at times constitute the source of infection (Menzani 1932). In both town and country the brunt of the disease is generally borne by *adult males*. The incidence is usually highest in the 15–45 age group, and is two to three times as high in males as in females. The age and sex incidence in country districts seems readily understandable, because of the predominance of male workers in contact with cattle, but in towns it is more puzzling. There is some evidence that in towns latent infections are commoner in women than in men, but that overt infections are commoner in men than in women (Harrison and Wilson 1928). The suggestion is that the greater consumption of raw milk in females confers on them an immunity which is often lacking in males, so that when the latter are exposed to infection, they prove more susceptible. Much the same argument has been used by Henricsson (1932) to explain why, in Sweden, more cases occur in the town than the country, namely, that the rural becomes better immunized than the urban population as the result of more frequent exposure to infection. Some workers (Hardy *et al.* 1931) have found that in towns males and females are affected more evenly than in the country, but there are numerous other observations to show that even in towns the adult male population provides the bulk of the cases.

Laboratory infections, though less common than with *Br. melitensis*, are by no means infrequent, and probably occur through contamination of the abraded skin or the conjunctiva with infective material (see Meyer 1933, Meyer and Eddie 1941). The incidence in veterinary surgeons seems to be definitely higher than in the general population, but the information available from different countries is rather conflicting (see Spengler 1929, Huddleson and Johnson 1930, Knoth 1930*a*, Makkawejsky and Karkadinowsky 1930, Thomsen 1932*a*, Wilson 1932*b*, Herrmann *et al.* 1934, Khaum and Liedl 1935). Quite a high proportion of those engaged in "cleansing" develop the peculiar skin rash to which allusion has already been made. Both infants and children suffer from the disease, but very much less frequently than adults.

(For general epidemiological studies and reviews of the disease, in addition to those already quoted, see Simpson and Fraizer 1929, Dalrymple-Champneys 1929, 1931, 1934, 1935; Darsin 1930, Wallace 1930, Atwood and Hasseltine 1930, Zeller 1931, Tebbutt and Marsh 1931, Cruickshank and Barbour 1931, Smith 1932*a*, Schittenhelm 1932, Hardy, Jordan and Borts 1932, 1936, Mackie 1933, Habs 1933*b*, 1935, Steyrer 1934, Meyer *et al.* 1934*a*, Meyer 1938, McNabb 1934, Report 1934, Giltner 1934, Beattie, Smith and Tulloch 1935, Wilson 1935, Taylor *et al.* 1938*a*, Huddleson 1939.)

Undulant Fever due to Br. suis

Probably the first diagnosed case of this disease was that described by Keefer (1924) in 1922 in the United States, though it was some time before the identity of the causative organism was realized. Clinically and bacteriologically the disease is similar to undulant fever caused by the *melitensis* and *abortus* types. Like *Br. melitensis*, *Br. suis* can be demonstrated more frequently in the blood stream than *Br. abortus*—possibly because of its greater ease of cultivation.

Epidemiologically, this disease is very much less extensive than the types already described. It is essentially an occupational disease, occurring among slaughterers and packers who handle the infected carcasses of pigs. The studies of Hardy and his colleagues (1931, 1932), of Huddleson, Johnson, and Hamann (1933*a*), and of Heathman (1934) in the middle western states of North America, have shown that a small amount of overt and a large amount of latent infection occurs in these workers. The organism apparently gains access through the abraded skin. Adult males are almost solely affected (Hasseltine 1930). Occasionally *Br. suis* infects cattle, and milk-borne outbreaks of undulant fever, without any special occupational incidence, are likely to occur (see Beattie and Rice 1934, Horning 1935, Borts *et al.* 1943). Brucella infection of pigs is far less common than contagious abortion of cattle. In consequence undulant fever due to *Br. suis* has hitherto been restricted mainly to the middle-west of North America, to Brazil, and to the Argentine.

Diagnosis of Undulant Fever

The occurrence of subclinical and atypical infections renders the clinical diagnosis of undulant fever peculiarly difficult, and all observers are agreed on the fact that large numbers of cases are missed. The final diagnosis can be made only by bacteriological examination. In practice it is well to regard every case of pyrexia of undiagnosed origin as possibly due to *Brucella* infection, and to bear this disease

in mind during the investigation of acute and chronic inflammatory conditions in which the diagnosis remains doubtful. Help is sometimes afforded by a blood count, which usually shows a secondary anæmia, a mild leucopenia, and a relative lymphocytosis.

Blood Culture.—In the febrile stages of the disease, an attempt should be made to isolate the causative organism from the blood stream.

The patient's blood should be withdrawn while the temperature is elevated, and preferably during the rise of a pyrexial wave. It should be distributed in 5–10 ml. quantities into two flasks containing 20–100 ml. of glucose broth, serum broth, Bacto tryptose broth, or liver extract broth. One of the flasks should be incubated aerobically, the other in an atmosphere in which 10–25 per cent. of the air has been replaced by CO_2. Subcultures should be made every 3–5 days on to a solid medium, and these should be incubated in the same atmosphere as the parent culture. Growth is often slow, and no culture should be discarded in less than 4–8 weeks. To guard against contamination, 1/20,000 Victoria blue (Hauptmann 1937), or 1/700,000 crystal violet (Huddleson 1939), may be added to the culture. Two ml. of the patient's blood may be inoculated intraperitoneally into guinea-pigs (Poston 1938). (For alternative methods of blood culture, see Elkeles and Fried 1932, Rainsford 1933, Hauptmann 1935*a*, Stewart *et al.* 1935.)

Though blood culture is positive in a high proportion of *melitensis* and *suis* infections, not more than 10–20 per cent. of *abortus* infections prove positive by this method. In *melitensis* infections the organism can often be isolated from the urine, provided repeated samples are examined (Kennedy 1905). Occasionally *Br. abortus* can be demonstrated in the bile (Amoss and Poston 1930, Leavell and Amoss 1931*a*) stools (Smith 1932*b*, Beattie *et al.* 1935, Goldstein *et al.* 1936) and tonsil (Carpenter and Boak 1932, Poelma and Pickens 1932).

Agglutination Test.—The most generally useful method is the agglutination test, first introduced by Wright and Smith in 1897.

Final dilutions of the serum should be put up ranging from 1/20–1/5120, and the tubes should be incubated for 18 hours in a 37° C. or 50° C. water bath. Though there is a considerable degree of cross-agglutination between *Br. abortus* and *Br. suis* on the one hand, and *Br. melitensis* on the other, it is advisable to use as agglutinating antigens strains corresponding to the prevailing type of infection. In countries such as Great Britain, Germany, Denmark, Sweden, Canada, and New Zealand, where practically all infections are due to the *abortus* type, this organism alone is necessary. Similarly in countries such as Malta, Corsica, Sicily, Southern Italy, Algeria, Tunis, Greece, and Palestine, where nearly all infections are due to the *melitensis* type, this organism suffices. But in countries or areas where two or three types of infecting organism are known to occur, such as France, Northern Italy, the United States, and parts of South America, it is advisable to use both a *melitensis* and an *abortus* antigen. Great attention must be paid to the preparation of the agglutinating suspension. Only strains that are absolutely smooth, as judged by the thermoagglutination and acriflavine tests, should be used. Routine suspensions should be made up from a number of strains. The organisms should be grown on liver extract or glycerol agar for 2–3 days, washed off with saline, and heated to 55° C. for 1 hour. The suspension should be standardized to match an opacity tube containing 1,000 million *Bact. coli* per ml., and preserved with 0·2 per cent. formol or 0·5 per cent. phenol. Suspensions prepared in this way will generally remain satisfactory for 3 months, but the moment signs of commencing stringiness appear, they should be discarded. For survey work, where large numbers of sera have to be examined, the slide method of agglutination may be used (see Huddleson and Abell 1928, Huddleson 1932, 1939, Welch and Mickle 1933).

The interpretation of the agglutination test is not always easy, and demands a knowledge of the clinical history and the occupation of the patient. Very much the same considerations affect the interpretation of this test as of that used in the diagnosis of enteric fever, and the reader may well refer back to Chapter 69 in which the relevant factors are discussed in some detail. The propositions we lay down must not be regarded as more than suggestions, applying particularly to this country. Each of them will necessarily be subject to exceptions. (1) A titre of 1/80 or less, in the absence of clinical symptoms, is indicative either of a latent *Brucella* infection, or of a past infection—not necessarily attended by definite disease. (2) A titre of 1/80 or over, in the absence of clinical symptoms or of a recent pyrexial attack, is suggestive of frequent infections, usually occurring in persons drinking large quantities of infected raw milk or exposed to contact with infected animals or carcasses. (3) A titre of 1/80 or over in the presence of pyrexia and other symptoms of disease, occurring in a person whose occupation or habits do not expose him to special risk, is very suggestive of active infection with a member of the *Brucella* group. In persons belonging to the occupational classes referred to, in whom a latent infection is not uncommon, a titre of 1/80 is too low to be of diagnostic significance. On the other hand, a titre of 1/1000 or over is rarely met with except as the result of an active infection, and may usually be regarded as evidence of undulant fever. (4) A titre of 1/20–1/80, in the presence of clinically undulant fever, may likewise be considered as practically diagnostic of this disease. (5) The complete absence of agglutinins from a patient's serum does not exclude the diagnosis of *Brucella* infection. Cases are on record in which a positive blood culture has been obtained in the presence of a negative agglutination reaction (see Gilbert and Dacey 1932, Heathman 1934, Taylor *et al.* 1938*a*). Agglutinins are generally present in a suggestive titre by the end of the 2nd week, and in frank cases of undulant fever they generally rise to a titre of 1/640 or more. After the attack is over they tend to fall fairly rapidly, and may sink to a low level within 3 months. There is evidence that in chronic cases they may fall even during the period of active infection, so that too much stress must not be laid on a negative agglutination reaction in patients whose pyrexia has lasted for some months.

Attention must be called to the not infrequent occurrence of a prozone, sometimes extending to even 1/640 in high-titre sera. For this reason a wide range of dilutions should always be put up (see Spencer 1930, Priestley 1931, Hirsch 1935).

Several observers have stated that the agglutinin titre to *Brucella* may be high in patients suffering from enteric fever, tuberculosis, and other febrile conditions. The evidence for this statement is not very satisfactory. Apart from the anamnestic reaction, which is not likely to account for more than a slight raising of the titre (see Amoia 1933), the most common cause of non-specific agglutination is the use of a suspension made from strains that are not absolutely smooth. Such strains are often agglutinated by normal serum, and apparently even more often by the sera of febrile patients. Their use in the past has been very common and has given rise to much confusion in the literature. Provided smooth strains only are used, it is justifiable to conclude that an elevated titre to *Brucella* is indicative of infection—latent, active, or past—with an organism of the *Brucella* group. (For recent references see Bayne-Jones 1930, Ranque and Senez 1932, Magliulo 1933, Morellini 1933, Sanfilippo 1933, Wilson 1930, 1934, Mohr 1935, Hauptmann 1935*b*.) We may add that there is no evidence that circulating agglutinins result from the alimentary absorption of milk containing antibodies (see Boak and Carpenter 1929, Peterson 1935).

The type of infecting organism may often be determined by use of the quantitative agglutinin absorption test, described in Chapter 34, carried out on the patient's serum (see Habs and Sievert 1935).

The *complement-fixation reaction* may be used to confirm the agglutination test, or in suggestive cases when the latter test is negative. Complement-fixing bodies are said to appear later in the serum than agglutinins, and to persist longer (see Sasano, Caldwell, and Medlar 1931, Morales-Otero and Monge 1932, Laun and Heide 1934). A precipitation reaction has also been described (Schlesmann 1932).

Brucellin Test.—In 1922 Burnet drew attention to an allergic skin test, performed by the intradermal inoculation into the arm of 0·05–0·1 ml. of a filtrate of a 20-day-old broth culture of *Br. melitensis* (*melitin*) or *Br. abortus* (*abortin*). A positive reaction is characterized by the appearance in 6 hours of a slightly raised, sometimes tender, œdematous plaque, 2–6 cm. in diameter, distinguished in colour from the surrounding skin. The reaction may disappear within 48 hours, or a central nodule may develop lasting for several days. Pseudo-reactions generally appear rapidly, and disappear within 24 hours. We have no space for an adequate discussion of this test. Its interpretation and value are rendered difficult by the fact that numerous preparations of brucellin (abortin or melitin) are in use. The potency of these is subject to considerable variation, and some of them give rise to reactions in normal persons. Not until a standard preparation and standard dose are used, will it be possible to assess the value of this test, Generally speaking, however, the reaction resembles the tuberculin test in denoting the occurrence of infection, without giving any clear indication as to its activity. In undulant fever it may not become positive for some weeks, but subsequently it remains positive, often for years. Its chief value will probably be found to lie in the diagnosis of chronic cases with a negative agglutination reaction, and in survey work for detecting the prevalence of *Brucella* infection (see Giordano 1929, Simpson 1930, Levin 1930, Leavell and Amoss 1931*b*, Straube 1932, Dubois and Sollier 1932*a*, Yeckel and Chapman 1933, Rainsford 1933, Huddleson *et al.* 1933*b*, Heathman 1934, Arbatskaia and Moroskin 1934, Goldstein 1934, Sarnowiec 1934, Olin 1935, Favorite and Culp 1935, Taylor, Lisbonne and Vidal 1935, Chiucini 1935). More recently Huddleson (1939) has described the preparation of a *Brucella* nucleoprotein extract called *brucellergin*, which he recommends for the skin test; 0·1 ml. of a 1/2,000 dilution is injected intradermally. A negative reaction is said virtually to exclude *Brucella* infection; a positive test indicates that the patient has been infected in the past or is infected at the moment (Gould and Huddleson 1937). Whether brucellin or brucellergin be used, it is important to remember that the injection of either may be followed by the appearance of circulating antibodies.

The difficulty of interpreting the skin reaction has led Huddleson, Johnson, and Hamann (1933*b*) to introduce the so-called *opsono-cytophagic test.* Briefly, this consists in incubating the citrated blood of the patient with a *Brucella* suspension for 30 minutes at 37° C., making films, and counting the number of organisms in 25 leucocytes. It is said that a weak or negative reaction in conjunction with a negative skin test is evidence of susceptibility, that a negative reaction in conjunction with a positive skin reaction points to active *Brucella* infection, and that a positive reaction to both tests is indicative of immunity. There is some discrepancy of opinion between different workers on the value of this test (see Meyer *et al.* 1934*b*, Veazie and Meyer 1935, Keller *et al.* 1936, Gould and Huddleson 1937, Keller, Pharris and Gaub 1938, Menefee and Poston 1939, Evans 1939, Castaneda *et al.* 1942, Tovar 1944).

For *post-mortem diagnosis*, cultures should be made from the spleen, liver, kidney and mesenteric glands, and incubated aerobically and in 10 per cent. CO_2. Alternatively, the ground-up organs may be suspended in broth and injected intramuscularly into guinea-pigs.

Prophylaxis and Treatment

The prevention of the disease in human beings consists ideally in the complete abolition of contact, direct or indirect, with infected animals or their products. Where infection is chiefly milk-borne, this may be comparatively easy. Either complete avoidance of milk, or its consumption only after pasteurization, boiling or sterilization, has been found in practice to be highly effective. Where, however, infection occurs mainly by contact, prevention becomes much more difficult. Vaccination of specially exposed persons may be tried, but there is as yet little evidence to show how far this method is likely to be successful.

Treatment of the disease itself is very unsatisfactory, and in spite of all measures the fever may continue for months or even years. The oral administration of dyes has been recommended by Leavell, Poston, and Amoss (1930). Several workers have claimed success by the use of intramuscular inoculation of autogenous or stock *Brucella* vaccines, given in a dose sufficient to evoke a smart febrile reaction and repeated every 3–7 days (see Schilling *et al.* 1931, Poppe 1933, Bianchi 1934). Di Guglielmo (1933) is supported by numerous observers in his claim for the therapeutic efficacy of intravenous administration of a *Brucella* vaccine. After one or two doses of about a million organisms to test the patient's sensitivity, doses increasing from 5 to 100 million are given every 3–4 days, till the temperature finally falls. Usually 7 injections, lasting over a month, are said to be required to bring about this end. Much the same results appear to be obtainable by protein shock therapy. Huddleson and Johnson (1933) and Huddleson (1939) in the United States, and Debono (1935) in Malta, have both reported favourably on the intramuscular injection of brucellin. Our own experience with this preparation has also been favourable.

It is advisable to test the patient's sensitivity by first inoculating 0·1 ml. into the skin. If there is little or no systemic reaction within 24 hours, treatment may be begun by the intramuscular injection of 0·5–1·0 ml. Further injections may be given at 3- or 4-day intervals, the dose being gauged so as to cause a brisk febrile reaction each time. In some cases one or two doses suffice to effect cure, but more often three or four are needed. If no reaction follows the first intramuscular inoculation of 1·0 ml., treatment will almost certainly prove useless. If the preliminary intracutaneous inoculation causes a systemic reaction, small doses only should be given, preferably by the intradermal route.

Serum treatment has been advocated (Hilgermann 1935), but judged by animal experiments its effectiveness is doubtful (Mitchell *et al.* 1935, Gwatkin 1938). Sulphonamide treatment has been recommended by a number of workers on the basis of one or two apparent cures, but observations on guinea-pigs hold out little promise of its success (Wilson and Maier 1939, 1940, Hamann and Huddleson 1939, Priestley 1940).

BRUCELLA INFECTION OF SHEEP AND GOATS

Reference has already been made, under the section dealing with undulant fever due to *Br. melitensis*, to infections of sheep and goats with this organism, and to the diagnosis of the disease by examination of the blood serum and milk serum for agglutinins. The disease exists particularly in countries along the Mediterranean littoral, in South Africa, and in some parts, notably Arizona, of the

United States. When first introduced into a herd, particularly during pregnancy, infection is frequently followed by a considerable number of abortions, but unless fresh animals are added, it dies down, and subsequent abortions are uncommon. The infection, however, usually becomes chronic, and may persist for months or years. In this stage it is often difficult to diagnose. The agglutination reaction may be negative. Some help is afforded by the intradermal melitin test. A suitable preparation, preferably a bacterial extract such as that described by Huddleson and Johnson (1933) or Taylor, Lisbonne, and Vidal (1935), is inoculated into one of the skin folds between the base of the tail and the margin of the anus. Readings are made after 24 and 48 hours. A positive reaction is characterized by œdema. Generally speaking, it may be said that a positive skin test indicates that the animal has been or is infected, while a positive agglutination test indicates that the infection is active. At post-mortem examination the organisms can be isolated most easily from the udder and the supramammary lymphatic glands. During life the organisms are often excreted in enormous numbers in the milk and the urine, while after abortion the vaginal discharge may remain highly infective for some days. Infection probably occurs mainly by contamination of the skin and mucosæ, though possibly the alimentary route may play some part. It seems to be more persistent in goats than in sheep. In both animals the young are less susceptible than the sexually mature.

Experimentally, the disease can be reproduced in both sheep and goats by feeding and by cutaneous, subcutaneous, intravenous, and intraperitoneal inoculation with virulent cultures of *Br. melitensis*. The disease so produced is often afebrile and, in spite of a septicæmia, symptoms may be lacking. Many of the animals, however, are unthrifty; their coats become thin; their weight diminishes; and a short hacking cough develops. Mastitis and arthritis are not uncommon; male animals may suffer from orchitis, while females, if infected during pregnancy, may abort. Death rarely occurs. Bacteriologically, the organisms are found in the blood for a variable time after infection. They then disappear, first from the peripheral blood and most of the viscera, then from the spleen and kidneys, then from the superficial lymph glands, and last of all from the mammary glands. The milk does not usually become infective for 2–3 months after inoculation or feeding. Agglutinins, sometimes reaching a high titre, are demonstrable in the blood serum, usually within a fortnight or so of infection (see Shaw 1906, Horrocks and Kennedy 1906, Zammit 1906, Eyre *et al.* 1907).

Experimentally, disease can also be produced in sheep and goats by *Br. abortus*, though natural infections with this organism seem to be rare. Bang (1897) induced abortion in a pregnant ewe by intravaginal injection of a pure culture of *Br. abortus*. Intravenous inoculation gave rise to uterine inflammation. Zwick (1910) found that both feeding and intravenous inoculation were successful in establishing infection in sheep. Infected ewes may go to term, yet the specific organisms may be found in large numbers in the vaginal discharge. Intravenous inoculation of *Br. abortus* into goats may give rise to abortion (Reinhardt and Gauss 1915). Zwick and Krage (1913) found that goats injected subcutaneously or intravenously might excrete the organism in their milk 24 hours later; the excretion was sometimes maintained for 8 weeks or more. Goats are also susceptible to conjunctival infection with *Br. abortus* (van der Hoeden 1933).

The control of the disease is beset with difficulties of an economic and social nature. Prophylactic vaccination, though recommended by Zammitt and Debono (1933), has so far not proved very successful. The ideal method is a policy of eradication (see p. 1715). All animals should be subjected to an agglutination and a skin test, positive reactors should be slaughtered, and breeding should be carried

out only from apparently uninfected animals. Herd tests should be made at 3-monthly intervals till no further reactors appear. If this policy is impracticable, the spread of infection should be limited as far as possible by elimination of all animals excreting the organism in the milk, by provision of separate boxes at the time of lambing or abortion, by abolition of communal pastures, by restriction of movement of animals from infected herds, and by control over the sale of animals for breeding. (For references to the general epizootiology and bacteriology of the disease see Report 1905–07, Segni 1931, Ananiadés and Miaoulis 1931, Dubois and Sollier 1932*b*, Pérès 1934, Moreno 1934, Meyer and Eddie 1935, Polding 1937, 1939, Taylor *et al.* 1938*b*, Zdrodowski 1938.)

It may be noted that abortion of sheep and goats is sometimes due to infection with *Salm. abortus-ovis*, a member of the *Salmonella* group (see Chapter 30).

CONTAGIOUS ABORTION IN CATTLE

Avortement épizoötique (French). *Seuchenhaftes Verwerfen* (German).

Contagious abortion in cattle is an infectious disease, due in the majority of cases to *Br. abortus* of Bang, and characterized by inflammatory changes of the uterine mucosa and fœtal membranes, resulting as a rule in the premature expulsion of the fœtus. Though regarded as contagious by Hutrel d'Arboval (1826) and Youatt (1834), (see Hutyra and Marek 1922), its infective nature was not shown definitely till 1878, when Lehnert transmitted the disease by intravaginal inoculation of pregnant cows with the vaginal discharge and placental tissue of aborting animals. In 1897 Bang, working with Stribolt, demonstrated microscopically a small Gram-negative bacillus in the uterine exudate of a cow with impending abortion, and succeeded in isolating it in pure culture. The intravaginal injection of this organism into two pregnant cows gave rise to abortion, and from the uterine exudate the organism was recovered in each case. Bang's work was confirmed by Preisz (1903) and Nowak (1908) on the Continent, by M'Fadyean and Stockman (1909) in this country, and by MacNeal and Kerr (1910) in America.

Epidemiology and Bacteriology

The disease is widespread throughout Europe, the United States of America, and most other countries of the world where there is a large cattle population. Its exact frequency is difficult to ascertain, but in this country Priestley (1934) estimates that 20 per cent. of the cows are infected. Similar high estimates have also been made for certain areas in the United States (Cotton 1931, Thomson 1932, Birch 1934). Large herds are more often infected than small. On account of the heavy loss from abortions, the frequent subsequent sterility of the animals, and the diminution in the milk yield, it is economically one of the most important diseases affecting cattle (Minett and Martin 1936). The fact, moreover, that infection may be transmitted to man renders the disease of public health interest.

Though clearly it is only pregnant animals that can display the typical symptom of abortion, infection may be conveyed by natural channels to cattle of any age and either sex. There is no distinct seasonal incidence. The commonest time for abortion to occur is from the 5th to the 8th month of pregnancy; 35·4 per cent. of cases occur in the 7th month alone (Wall 1911). Judged from experimental

work, the incubation period is variable; according to Mohler and Traum (1911) it may last from 1 to 33 weeks.

Introduced into a fresh herd the disease may spread rapidly, assuming epidemic proportions. Provided that no new animals are imported, it loses its initial severity, passing into an endemic state in which, if no preventive measures are taken, it remains for some years. A pregnant animal becoming infected for the first time generally aborts at an early stage; at its next pregnancy abortion occurs either not at all, or not till a later period; and though abortion may be repeated on a third occasion it is much commoner for the calf to be delivered at full term. Bang (1897) reports that of 83 cows only 30 aborted in 2 successive years, and only 6 three times in succession. From this it may be gathered that an immunity is acquired which is usually sufficient to protect the animal against further attacks of the disease.

The bacillus may, however, remain alive in the tissues of the cow for a considerable length of time. Bang (1897) found it in the uterus of a cow 9 months after the fœtus had died and become mummified. As a rule the uterus frees itself quickly, and the specific organism takes refuge in the udder and often in the supra mammary and pelvic lymphatic glands, where it may persist for months or even years (see Doyle 1935). Under favourable conditions it may be demonstrated in the blood stream, and occasionally in the urine and fæces (see Fitch, Bishop, and Boyd 1932*a*). Its frequency in the circulating blood is a little doubtful. Soule (1930) isolated it from about 10 per cent. of cows containing serum agglutinins, and Lübke (1935*a*), in a smaller series, from 22 per cent. Other workers, on the contrary, have failed to find it at all, or have found it in only a small proportion of animals (Fitch *et al.* 1932*a*, Krüger 1932, Doyle 1935, and numerous others). Probably the stage of the disease is important, and positive cultures are more likely in the early acute than the late chronic stage. Infection occurring in non-pregnant animals, particularly before sexual maturity is reached, may remain latent or may actually retrogress. In cows the organism frequently settles in the udder; abortion may or may not occur at the next pregnancy. In calves and young heifers the organism disappears completely from the tissues within a few weeks or months. In the udder *Br. abortus* gives rise to small subacute or chronic inflammatory foci situated in the alveoli, the interalveolar connective tissue, and along the lactiferous ducts (Runnels and Huddleson 1925, Ridala 1936). The lesions are too small to be detectable by clinical examination.

From the udder the organisms are excreted in the *milk*. This important fact was first demonstrated by Schroeder and Cotton in 1911. Karsten (1932) found that the proportion of aborting cows in which the milk was subsequently shown to be infected varied on different farms from 24 to 70 per cent., while in infected herds 19–33 per cent. of cows that did not abort excreted the organisms in their milk. Sheather (1923) observed that 34 per cent. of cows giving a positive blood serum agglutination reaction were yielding infected milk. Numerous similar observations have been made by different workers. For example, Pröscholdt (1932) found that 53 per cent. of cows with a blood serum agglutinin titre of 1/100 or over were excreting *Br. abortus* in the milk. The same author observed that, of 208 cows whose milk was infected, 145 had aborted, while 63 had calved normally. Lerche (1931) gives very similar figures. The organisms may appear in the milk within 1 or 2 days of abortion, and are usually demonstrable within a week, though in some animals as long as 5 months may elapse before excretion commences (Wall 1930). Many

cows cease excreting the organism after a few weeks, but others may remain infected for a year or two, or even permanently. In Pröscholdt's series, out of 145 aborting animals whose milk was infected, 22 had aborted 1–2 years previously. The excretion is irregular and often intermittent. The number of organisms present fluctuates from day to day. It is usually highest at the commencement of lactation, and gradually falls. Except in the first week or two of lactation, when there may be as many as 200,000 per ml., it is uncommon for the milk on withdrawal to contain more than 30,000 per ml. (Bang and Bendixen 1932*a*, Stockmayer 1936); the usual number is 10–2000 per ml. (Karsten 1932). Infection of the milk may be as heavy after normal calving as after abortion (Stockmayer 1936). Disease is often confined to one or two quarters of the udder. The hind-quarters are more often affected than the fore, and the right hind-quarter seems to be affected more often than the left (Bang and Bendixen 1931, Thompson 1934, Doyle 1935).

Though the organism commonly responsible for the disease is *Br. abortus*, numerous observations have shown that cattle in close contact with infected goats or sheep may become infected with *Br. melitensis* (see Taylor, Vidal, and Roman 1934, Benussi 1935). The infection seems to be localized mainly in the udder, and abortion is uncommon. Similarly in large hog-raising districts, cattle may become infected with *Br. suis* and excrete this organism in the milk (see Beattie and Rice, 1934, Molinelli and Ithurrat 1934).

Mode of Infection and Experimental Reproduction of the Disease.—There has been a long dispute over the commonest mode of infection. Cattle are so easy to infect experimentally, not only by dirt inoculation into the tissues, but also by the natural passages, that it is very difficult to decide on the route usually followed in the natural spread of disease. The three main portals are:

(1) The Mouth.—Bang (1906) and others have shown that it is possible to reproduce the disease in pregnant heifers and cows by feeding them with infective material, and have therefore suggested that infection probably occurs through contaminated fodder. It is known that the uterine exudate which is voided at the time of the abortion is extremely infective, that the bacilli may remain alive in it for some time—for 7 months if kept in the ice-chest (Bang 1897); that the aborted fœtus or fœtal membranes deposited on grass and left at atmospheric temperature shielded from direct sunlight may remain infected for as long as 6 months (Bosworth 1934–35); and that unless strict isolation of the animals is practised, there is ample opportunity for contamination of the pasture and other food material. A further source of infection is the milk of the aborting cows, which often contains *Br. abortus* in large numbers. Rats have been accused of spreading infection (Karkadinovsky 1936), but there is little evidence to support this (see Bosworth 1940).

(2) The Vagina.—In his original experiments Bang (1897) demonstrated the possibility of infecting pregnant cows by intravaginal inoculation of pure cultures. This has been confirmed frequently (Report 1909, M'Fadyean *et al.* 1913, Seddon 1919). It seems, therefore, not improbable that contamination of the vagina with infected soil or litter may be responsible for naturally acquired infection. A second method by which vaginal infection may occur is sexual intercourse. Bulls may be infected by injection of pure cultures under the prepuce (M'Fadyean *et al.* 1913). Injected intravenously, the organisms may lodge in the testicles and be excreted in the seminal fluid (Seddon 1919). Experimentally these facts are sufficient to indicate that the bull may play an active part in conveying the disease to cows. There is still stronger evidence from the epidemiological side, sufficient without doubt to incriminate the bull (Bang 1897). Moreover, the agglutination test shows that bulls are not infrequently infected by *Br. abortus*; Holth (1911) found agglutinins in the blood of 3 out of 28 bulls which he examined.

(3) THE SKIN AND CONJUNCTIVA.—Attention has been drawn to these routes of infection by Bang (1931), Bang and Bendixen (1932*b*), Cotton and Buck (1932), and Cotton, Buck and Smith (1933). Experimentally it has been found possible to infect animals fairly readily with *Br. abortus* by means of an infected compress left for a variable length of time in contact with the abraded, or even intact, skin. Infection has also followed simple conjunctival instillation of an *abortus* suspension.

Which of these three routes is the most important in practice, we have at present no exact means of telling. The Departmental Committee set up by the Board of Agriculture to investigate the disease considered that feeding was the most common method, that vaginal infection held second place, and that sexual infection probably played quite an insignificant part. Contamination of mucosal and skin surfaces must almost certainly be responsible at times for infection, but on the whole the prevalent opinion still seems to favour the alimentary route (see Mieszner 1931). Considering the frequency with which *Br. abortus* is excreted in the milk, and the ease with which animals can be infected by the udder (Schmidt 1932), it seems probable that infection must at times be transmitted from infected to normal cows at the actual time of milking. Unless the normal animals are milked first, contaminated milk must be rubbed into the teats, thus giving the organisms an opportunity to penetrate the skin or to enter the teat canal. There is still a wide field open for investigation. *The aim must be, not to ascertain whether a given route of infection is ever taken under natural conditions, but what the frequency distribution of the possible routes of infection really is.* Exact knowledge of this type may prove of great service in controlling the spread of infection in the field.

That the experimental reproduction of the disease can be readily accomplished by oral and parenteral inoculation was shown by the earlier workers. The interest of these experiments centres on the effect produced at different stages in the animal's life history. It is abundantly clear that inoculation during pregnancy is frequently followed by abortion, and by permanent infection of the udder and lymphatic system. The time between infection and abortion is said to be inversely proportional to the length of pregnancy (Thomsen 1937*b*). In calves and non-pregnant heifers, on the other hand, infection appears to be restricted to the reticulo-endothelial system (see Lübke 1935*b*), and usually dies out within a few weeks or months, leaving behind it an appreciable degree of immunity to fresh infection. This behaviour is now made use of in prophylactic vaccination (see p. 1716). The agglutinins that occur as a response to infection in the calf generally disappear within a year.

We may add that cattle may be infected, not only with *Br. abortus*, but also with *Br. melitensis* and *Br. suis*. These organisms settle readily in the udder, but less frequently give rise to abortion (see Zeller and Beller 1934, Thomsen 1934). Provided freshly isolated smooth strains are used, *Br. abortus* from the blood of human patients suffering from undulant fever seems to be fully virulent for young heifers (Birch and Gilman 1935). There is no satisfactory evidence that *abortus* strains of human and bovine origin differ in virulence for man or animals, though few direct observations, with the necessary precautions, have yet been made on this point.

Diagnosis

In the yellow or dark-brown mucoid exudate found between the uterine mucosa and the chorion, large numbers of *Br. abortus* may be demonstrated microscopically, aggregated into clumps within the polymorphonuclear cells. The organism may

likewise be seen in smears made from the gastro-intestinal contents of the fœtus. Provided the material sent for examination is fresh and uncontaminated, a provisional diagnosis may often be made microscopically ; as a rule, however, cultural or inoculation methods are required.

Cultivation.—The organism is best grown by seeding glycerine, or liver, agar slopes with the uterine exudate, or with the stomach contents of the fœtus, and incubating them in an atmosphere of air containing 5–10 per cent. of added CO_2 (Smith 1926, Huddleson *et al.* 1927). (See Chapter 34.) If uncontaminated, the organisms will form characteristic lenticular colonies in the course of 2 or 3 days (Fig. 173, p. 819). Their identity should be confirmed by agglutination. The bacilli are sometimes found in the blood and in the liver of the fœtus, but less abundantly than in the stomach. If the material is not pure, it is best to resort immediately to guinea-pig inoculation. The material is ground up in Ringer's solution, and 0·5 ml. injected intramuscularly into two or three guinea-pigs. The animals are killed after 4–8 weeks, the blood is examined for agglutinins, and cultures are made from the sublumbar glands and the spleen (see "Milk" below). At post-mortem examination of slaughtered cattle the organisms are most likely to be found in the udder, and in the supramammary, iliac, and pharyngeal glands. They may be sought for by direct culture and by guinea-pig inoculation (see Doyle 1935). Any obvious lesions, such as hygroma of the knee (v. d. Hoeden 1932*a*), should also be examined.

Agglutination Reaction.—In practice this is the most widely used method of diagnosis. Although the agglutination test in cattle does not differ in principle from that in man, it is necessary to consider separately its interpretation in relation to the titre that may be observed.

The test may be carried out by the tube or the slide method (for technique, and preparation of antigens, see Huddleson and Abell 1928, Huddleson 1932, 1939, Welch and Mickle 1933, Fitch and Donham 1933, Donham and Fitch 1934*a*, *b*, 1935, Welch and Marsh 1935). Final serum dilutions of 1/10–1/2560 should be put up. Intermediate zone phenomena are frequently encountered (see Priestley 1931).

The interpretation of this test is often difficult, and is not rendered any easier by the fact that, owing to differences in technique, the titres of different workers may not be strictly comparable.

Calves, even those born of infected mothers, give a negative serum reaction at birth. If, however, they are allowed to suck infected dams within the first 24 hours of life, agglutinins become demonstrable in their serum within about 2 hours. This appears to be due to the absorption through the alimentary tract of antibodies present in the colostrum. Calves passively immunized in this way lose their agglutinins very rapidly (McAlpine and Rettger 1925). Even calves that are actively infected and develop agglutinins some time after birth appear to lose them within 6 months, unless reinfection occurs (Thorp and Graham 1933).

In an animal that is infected during pregnancy the titre generally rises before abortion to 1/200–1/1000 or over. During the following 6 months it tends to fall. If the cow becomes a chronic carrier, the titre usually remains fairly high. About 80 per cent. of cows with a persistent titre of 1/200 or over are found to be excreting *Br. abortus* in the milk, while a titre of 1/1000 or over is almost diagnostic of udder infection. If animals are followed for any considerable length of time, the agglutinin titre of positive reactors will often be found to decline. This is particularly true of low reactors. Damon (1932), for example, who observed a herd with a mean complement of 225–250 animals over a period of 4 years, found that 27·7 per cent. of animals reacting at 1/25, 17 per cent. of those reacting at 1/50, and 5 per cent. of those reacting at 1/100 or over lost their

agglutinins permanently (see also Hadley and Welsh 1931). Huddleson and Smith (1931), however, found that, of a total of 247 animals reacting at 1/25 or over, and followed up for a period of 1–8 years, only 4 became permanently negative. Animals that abort usually have a considerably higher titre than non-aborting animals. A few animals may fail to show any agglutinins at the time of abortion, and for a few days afterwards; most of these become positive within 2–3 weeks, but there is some evidence that others may fail completely to develop agglutinins. Animals may certainly excrete *Br. abortus* in the milk and yet fail to show agglutinins in the blood serum or whey (Karsten 1932).

The interpretation of a single test is often difficult, and depends on whether infection is known to be present in the herd. Many workers regard a titre of 1/20 or 1/25 as strongly suggestive of infection, whereas others pay little or no attention to a titre of less than 1/100. Our own view is that a titre of 1/25 cannot be disregarded, particularly if occurring in an infected herd. The only satisfactory method, however, is to make monthly tests on all suspicious animals, so as to detect as soon as possible those that become definitely positive. It must always be remembered that, though a positive test is a practically certain indication of infection, a doubtful or negative test cannot be held to exclude infection. (For interpretation of reaction see also Zwick 1910, Grinstadt 1910, Wall 1911, M'Fadyean and Stockman 1912, Seddon 1919, Smillie, Little and Florence 1919, Mathews 1924, Jordan and McBroom 1932, White *et al.* 1933, Ranney 1936, Kitselman 1936, Fitch *et al.* 1937.)

Complement-Fixation Reaction.—The complement-fixation test gives results very similar to those of the agglutination test. Mohler and Traum (1911), who examined 400 sera by both methods, found close agreement between them; in only five instances were the results at variance. Similar results were recorded by Wall (1911), Reinhardt and Gauss (1915), Zwick (1910), and others. Mitchell (1929) considers that both tests are desirable, while Lentz (1932) prefers the complement-fixation test. Holth (1911) demonstrated the value of the complement-fixation test in cases of abortion in which the products obtainable for examination were badly contaminated; if the placenta is ground up in saline, heated to boiling-point and filtered, it can be used as an antigen.

The Abortin Reaction.—Abortin is a substance analogous to tuberculin, which was introduced by M'Fadyean and Stockman (1909) in an attempt to elaborate a diagnostic test based on the hypersensitiveness of infected animals. It is prepared from a 4 to 6 weeks' glucose glycerine broth culture, which is sterilized at 99° C. for 2 hours, filtered through a Berkefeld candle, evaporated to 1/10 of its bulk, and preserved with 0·5 per cent. phenol. The dark syrupy liquid thus obtained is suitably diluted before use, and injected subcutaneously. In a positive reaction the temperature rises to 104–106° F. As a method of diagnosis, this original abortin did not find favour; the authors themselves after extensive trials were disappointed with it (Stockman 1914). Nor did Holtum's (1928) heat-killed suspension of *abortus* in phenolized saline meet with success. Probably a bacillary extract, such as that prepared by Huddleson and Johnson (1933) or Taylor, Lisbonne, and Vidal (1935) might be found satisfactory. Further observations are badly needed on the use of this test, preferably carried out by the intracutaneous inoculation of abortin into the caudal fold. A few promising reports of the test have been made of recent years (Dubois and Brune 1933, Dubois 1934, Rossi and Vigel 1934, Franco and Pezzi 1935), and it might prove valuable in the detection of agglutinin-negative animals. Mirri (1935) recommends a palpebral test.

Demonstration of Br. abortus in Milk.—Examination for the presence of *Br. abortus* in milk may be conducted by cultural or by animal inoculation methods.

Cultivation.—Cultural methods are satisfactory only with milk samples from individual cows collected under relatively aseptic conditions. Separate quarter samples should be taken, and either kept refrigerated, or preserved with 0·5–1·0 per cent. boric acid, till the time of examination. The whole milk, the gravity cream, or the deposit from high-speed centrifugation should be streaked on to a number of plates of liver extract agar, or 2 per cent. glycerol agar containing 10–15 per cent. of ox serum. Contaminating organisms may be partly suppressed by the addition to the medium of gentian violet and malachite green. The exact concentrations of these dyes vary according to the manufacturer; usually a final concentration of 1/100,000 to 1/200,000 is satisfactory. The plates should be incubated in 5–10 per cent. CO_2, and examined at intervals for 14 days (see Huddleson *et al.* 1927, Hasley 1930, Traum and Henry 1930, Karsten 1932, Pröscholdt 1932, Karsten and Bischoff 1933, 1934, Stockmayer 1933*a*, 1935).

Animal Inoculation.—If the animal method is chosen, it is advisable to inoculate a mixture, composed of 2 ml. of gravity cream and the deposit from 100 ml. of milk after high-speed centrifugation, intramuscularly into the hind leg of each of two guinea-pigs. Alternatively 4 ml. of whole milk may be injected, 2 ml. into each thigh. The animals should be killed about 6 weeks later. At post-mortem examination the femoral and sublumbar glands will be enlarged and pale; the spleen may be enlarged, its surface slightly irregular, and a few small greyish-yellow necrotic foci may be present. The liver may show two or three tiny necrotic foci. The macroscopic lesions are often inconspicuous, and must on no account be relied upon for diagnosis. The blood serum should be tested for agglutinins; a titre of 1/25 or over is highly suggestive of infection. Cultures should be made from the sublumbar glands and spleen, and all suspicious organisms identified by agglutination and other methods. In not all animals containing serum agglutinins is it possible to isolate the organisms from the tissues. On the other hand, it is uncommon to isolate them in the absence of a positive agglutination reaction. Individual guinea-pigs vary considerably in their susceptibility to *Br. abortus*, and it is common to obtain positive results in one animal and negative in the other (see Smith 1932*b*, Plate 1934*a*). If tubercle bacilli are present in the milk simultaneously with *Br. abortus*, the guinea-pig will suffer from a double infection. The diagnosis of tuberculosis can be made on the basis of the macroscopic lesions and the demonstration of acid-fast bacilli in the organs. The diagnosis of *abortus* infection can be made on the basis of the agglutination reaction and the cultivation of the organisms from the tissues. Pullinger (1936), however, has pointed out that the tubercle bacillus interferes with the development of *Br. abortus* in the animal body, so that the demonstration of this organism may often be unsuccessful in milk coming from cows with tuberculous mastitis.

All workers are agreed that the animal inoculation method is more satisfactory for the demonstration of *Br. abortus* in milk than the direct cultural method. Plate (1934*b*) found that 90 per cent. of infected samples were positive by the animal and only 50 per cent. by the cultural method. Similarly Karsten and Bischoff (1934), who examined 466 milks by both methods, obtained 184 positive results by the guinea-pig and 101 by the cultural method. It is not uncommon to obtain occasional positive results by culture, when the animal inoculation results are negative, so that it is advisable to use both methods. In mixed milk, or in milk of single animals that has not been drawn aseptically and kept cold, the animal inoculation method is the only suitable means of demonstrating *Br. abortus*.

Serological Examination of Milk.—Indirect evidence of infection of the milk may be obtained by examination of the whey for agglutinins or complement-fixing bodies. The whey may be obtained by adding 1 drop of rennet to 5 ml. of skim milk, incubating at 58° C. for 30 minutes, breaking up the clot, and centrifuging. Alternatively 5 ml. of carbon tetrachloride may be added to 10 ml. of milk, together with a small quantity of rennet. The milk is corked, and shaken for several minutes till the fat is extracted.

It is then incubated for 1 hour, and centrifuged (Hall and Learmonth 1933). The advantage of 58° C. for incubation is that it destroys any complement present. The agglutination test is carried out in the usual way. Control tests must be put up, since non-specific reactions may occur. A whey agglutinin titre of 1/80 or over affords a high probability that the udder is infected and that *Br. abortus* is being excreted in the milk. The higher the titre, the more probable this is. Similarly, fixation of complement with 0·05 ml. of whey is strongly suggestive of milk infection.

Examination of the whey for antibodies is sometimes used as a method of detecting infection of the animal with *Br. abortus*. Except as a preliminary means of investigation, this procedure is unsatisfactory, because only a proportion of infected animals containing blood serum agglutinins give a positive whey reaction. (For references to use and interpretation of whey test, see M'Fadyean and Stockman 1909, Seddon 1915, Robinson 1919, Sheather 1923, Graham and Thorp 1930, Gilman 1930, Hasley 1931, Norton and Pless 1931, Berge and Ekrem 1932, 1934, Pröscholdt 1932, Karsten 1932, Karsten and Bischoff 1933, 1934, 1935, Plate 1934*a*, *b*, Caldwell, Parker, and Medlar 1934, Molinelli and Ithurrat 1934, 1935, Smith 1934*a*, *b*, van Oyen 1934, Doyle and Beckett 1936.)

Prophylaxis and Treatment

At the time of abortion the uterine discharge is highly infectious; the usual measures must therefore be taken for isolation of the animal, and subsequent disinfection of its stall. The fœtus and membranes should be burned, or buried in lime. Irrigation of the cow's vagina should be practised with an antiseptic solution for a week or till all discharge has ceased, and not till some considerable time has elapsed since the complete cessation of the discharge should the cow be taken to the bull. If a bull has served an animal that has recently aborted, it is well to irrigate its penis and preputial sheath with an antiseptic solution, in order to prevent active infection of the bull, or passive carriage of the organism to another cow. Calves born of infected cows are better brought up on milk from another animal.

Eradication of Contagious Abortion.—The ideal policy is the complete eradication of infection. Various methods are recommended for doing this. The general principle consists in the detection of infected animals by the agglutination or complement-fixation reaction, the segregation or sale of positive reactors, and the building-up of a clean, non-infected herd. The degree of success attending this policy varies with a number of factors. With a small or medium-sized herd, particularly if self-contained and protected against infection from water, manure, and other animals, with provision of calving boxes, and re-testing of non-reactors every 2 months so as to eliminate all animals as soon as they become positive, it is often possible to eradicate the infection entirely and to maintain a healthy herd for several years. On the other hand, with very large herds, particularly if not self-contained, with flying herds, with farms on which adequate accommodation for segregation of infected, and quarantine of newly imported, animals is impossible, and with imperfect control over infection from other sources, the results are often disappointing. Generally speaking, if the conditions are favourable, and if the disease is not at the height of its activity, this policy should be adopted, since its success is followed by the improved general health of the herd, better and more regular breeding, and an increased milk supply. Success, however, cannot be guaranteed. One of the greatest problems at the moment is presented by the infected non-reactor, which may abort, or excrete *Br. abortus* in the milk, and so contaminate the other animals in the herd (see Bang 1906, M'Fadyean 1921, 1924, Giltner 1924, Thomsen

1928, Zeller 1931, Henricsson 1932, Kitselman 1932, Newsom and Cross 1932, Clark 1932, Mitchell *et al.* 1933, Fritz and Barnes 1933, Birch 1934, Birch *et al.* 1934, van Oyen 1934, Report 1935, Thornshaug 1937, Gilbert 1937).

Vaccination.—Early observations by Bang (1906), M'Fadyean and Stockman (1909) and Stockman (1914) suggested that the inoculation of non-pregnant heifers or cows with a living vaccine of *Br. abortus* was able to confer some degree of immunity on the animals, as shown by a lower abortion rate. During the next 20 years or so vaccination, usually with strains of modified virulence, was used fairly extensively, and numerous papers were published on the results (for references, see Topley and Wilson, 2nd ed., p. 1355). Little fresh knowledge, however, was gained, chiefly because few observations with properly controlled groups of animals were made. More recently a great deal of attention has been devoted to the preparation of a standardized vaccine, and much valuable information has been forthcoming. It has been found that the more virulent the vaccinal strain is, the greater is the degree of subsequent immunity; but that in practice the use of a fully virulent strain is inadvisable, because of the danger partly to pregnant animals in the herd and partly to the human population if it is excreted in the milk. A strain of modified, and preferably fixed, virulence is preferable. Such a strain was introduced by Buck (1930) in the United States under the name S 19, and has since been used with good effect for the vaccination of calves and non-pregnant heifers and cows (for references, see Haring 1938, 1939, Haring and Traum 1937, 1941, McEwen 1941, Huddleson 1942). There is some evidence that the immunity so conferred persists even to the second pregnancy, but it is probably wiser to revaccinate the animals before being taken to the bull. One disadvantage of vaccination with the S 19 strain is that it stimulates the formation of antibodies and thus interferes with the normal interpretation of the agglutination reaction. To overcome this objection, McEwen (1940*b*) has introduced another strain of modified virulence, Strain 45 (20), which does not call forth agglutinins and which can therefore be used in clean herds in which the eradication policy is being pursued.

It is still too early to say how far the use of live vaccines will succeed in paving the way towards the complete elimination of contagious abortion. Present evidence suggests that it raises the degree of immunity of the individual animal to a level at which multiplication of the fully virulent organism, when this gains access to the tissues by natural channels, is restricted. Unlimited multiplication in the uterus and udder is prevented, so that abortion and infection of the milk are much less frequent than in uninoculated animals. This, in its turn, should lead to a diminution in the total amount of infective material excreted, and thus lessen the danger of infection both of other animals in the herd and of human beings consuming raw milk.

One danger of the live vaccine is that the strain may regain its virulence in the animal body. That this is not a hypothetical risk has been shown by McEwen (1940*a*). For this reason attempts are still being made to make use of a *dead vaccine*. In spite of the earlier statements, there seems no reason why properly killed organisms, given with due regard to size and spacing of dosage, should not afford protection almost as good as that conferred by living organisms. Already Huddleson (1943) has obtained promising results on guinea-pigs with organisms killed by mechanical crushing, and experiments in this country with organisms killed in a different way have yielded very hopeful results.

BRUCELLA INFECTION OF SWINE

This disease has only recently been recognized, and is of limited distribution. It first attracted serious attention in the large hog-raising districts of the middle western States of North America. According to the observations of Boak and Carpenter (1930), Feldman and Olson (1934), and McNutt (1935) about 2 per cent. of animals destined for the abattoirs are infected in this area. In Europe, the disease has been recognized in several countries, but with a few exceptions it appears to be mainly of sporadic occurrence (Thomsen 1931, 1934, 1937*a*, Knoth 1930*b*, Saxer 1936, Steffens 1937). A focus of infection has been found in White Russia (Makkawejski *et al.* 1933). The disease appears to be not uncommon in Brazil (see Neiva 1934) and the Argentine. It has been observed in New South Wales (King 1934). In this country it has not so far been detected (see Doyle 1934).

Bacteriologically, all outbreaks appear to have been due to *Br. suis*, and all of them, with the exception of the Danish epizoötic, to the American type (see Chapter 34), though complete information has not always been available on this point. The disease is essentially an infection of the reticulo-endothelial system, with the production of inflammatory disturbances in the glands, joints, and reproductive organs. Contrary to contagious abortion of cattle, in which the females are chiefly affected, the disease in swine attacks mainly the *boars*. Abortion, though it does occur, is much less frequent than in cattle. Abscess formation is met with in the submaxillary, cervical, inguinal, and popliteal lymph glands. The joints of the hind legs, particularly the knee and hock, are frequently affected; they are swollen, painful, frequently contain fluid, and sometimes ankylose. Epididymo-orchitis is very common. In Makkawejski's series, no fewer than 269 out of 786 boars showed orchitis, usually bilateral. The affected testicles are sometimes of enormous size, reaching 6½ lb. in weight, and purulent foci, which may undergo calcification, are not infrequent. Multiple foci may also be present in the vesiculæ seminales. *Br. suis* may, however, often be demonstrated in the tissues in the absence of macroscopic pathological changes.

In *sows* a condition for which Thomsen (1934) suggests the name "miliary brucellosis of the uterus" is frequently met with. The interior of the uterus is studded with small yellowish-white nodules located in the deeper layer of the mucosa and projecting slightly above the surface.

The disease can be readily reproduced by feeding and by conjunctival inoculation. According to Stockmayer (1933*b*), pigs are susceptible to *Br. abortus* as well as to *Br. suis*, though no outbreaks due to *Br. abortus* have yet been recorded in the field. Thomsen believes that natural infection is spread to a considerable extent by copulation, though this of course will account only for transmission of the disease to sexually mature animals. Infection of the conjunctiva by urine, and alimentary infection probably play a part. Sucking pigs are readily infected. It is possible that infection occurs through the milk of the mother, though invasion of the udder is uncommon.

In the field, *diagnosis* is best made by the agglutination and complement-fixation tests on the blood serum. A titre of 1/100 is regarded as definitely positive, 1/50 as strongly suggestive, and 1/25 as doubtful. Some help may be given by the intradermal test (Thomsen 1934). In the abattoir, the blood serum should be examined, and a search made by culture and guinea-pig inoculation for *Br. suis*

in the tissues. According to Johnson and Huddleson (1931) and Johnson, Huddleson, and Hamann (1933), the organisms are commonest in the spleen, gastric and supramammary lymph glands, and the liver. Numerous other organs may be infected, but less frequently.

The disease is of undoubted economic importance, owing particularly to impotence in the boars and abortion or sterility in the sows. But it is probably of even more importance in its effect on public health. Already large numbers of cases of undulant fever have been ascribed to it, and it affords a very real hazard for workers in abattoirs and packing houses. So far as reports go, it would seem to be fairly amenable to control by the eradication policy. In Denmark, by the institution of such a policy, involving slaughter of infected animals in lightly infected herds, and slaughter of all animals in heavily infected herds, it proved possible to stamp out the disease entirely within a very short time. Johnson, Huddleson, and Hamann (1933) in the United States have been successful with a less radical policy, involving blood testing once a month, followed by segregation and ultimate elimination of the positive reactors. The seasonal breeding of sows makes control of the disease considerably easier than in cattle. (For further information on this disease the reader is referred to the excellent monograph of Thomsen 1934.)

BRUCELLA INFECTION OF HORSES, DOGS, CATS, FOWLS AND RATS

Horses.—Following on the work of Rinjard and Hilger (1928) in France, *Brucella* infection of horses has now been recognized in a number of European countries (see van der Hoeden 1931, Makkawejsky *et al.* 1931, Panisset and Delbé 1932, Hieronymi and Gilde 1934, Duff 1937, Thomsen 1937*a*), in the United States (Fitch, Delez, and Boyd 1930), and in Australia. In Holland van der Hoeden (1932*d*) found that 72 out of 482 horse sera, mostly taken from the slaughter-house, agglutinated *Br. abortus* to 1/100 or over. In this country Priestley (1934) obtained evidence that 5–15 per cent. of horses had specific antibodies in their blood. The incidence in males and females was much the same, but older horses seemed to be more often infected than younger. Since agglutinins are said to be present in normal horses up to a titre of 1/50 or 1/100, estimates of the incidence of infection based on agglutinins alone should be accepted with caution (see Krüger 1937, Deem 1937). The disease may be contracted from other horses or from cattle. Though the infection frequently remains latent, in a certain proportion of animals it is accompanied by the appearance of suppurative lesions, particularly on the head and neck (poll-evil, fistulous withers), and less often of bone abscesses, arthritis, and tenosynovitis. Their appearance may be preceded by fever and weakness. No history of local trauma is usually obtainable. The inflammation is extremely painful, and lasts for a few days to several months. The abscess may disappear by absorption, but more often it breaks down at multiple points on the surface, and discharges a yellowish viscous fluid containing fibrinous clots. Bacteriologically *Br. abortus* can usually be isolated, or sometimes in the United States *Br. suis*, though secondary infection of the fistulæ readily occurs. Horses can be infected experimentally with *Br. abortus* by feeding or parenteral inoculation (v.d. Hoeden 1932*b*, *d*, Schneller 1934); but according to Fitch, Bishop, and Boyd (1932*b*) the local manifestations of the disease cannot be reproduced except by direct inoculation

into the neck ligament. The opinion is expressed by van der Hoeden (1932*b*, *d*) that poll-evil is essentially an allergic manifestation. It was found, for example, that if dead *abortus* bacilli were injected subcutaneously into an infected animal, a local abscess formed from which living organisms could be cultivated. Bacteriological diagnosis of infection is made by the serum-agglutinin test ; a titre of 1/200 may be regarded as positive, and 1/100 as suspicious. An allergic test may also be used, the ophthalmic (v.d. Hoeden 1932*b*, *d*) or the intradermal (Rossi and Saunié 1934) route being chosen. Horses may convey infection to cattle (White and Swett 1935), and in any eradication scheme the two animals should be kept separate.

Dogs.—*Brucella* infection of dogs appears usually to be of the inapparent type. Symptoms of disease are uncommon, and though occasionally metritis or local abscess formation may occur, the infection can usually be diagnosed only by examination of the blood serum for agglutinins and complement-fixing bodies. The disease seems to be not infrequent in both Europe and America. In some surveys 2–10 per cent., or even more, of dogs have been found to be infected (v.d. Hoeden 1932*c*, Thomsen 1932*b*, Grandi 1933, Feldman, Mann, and Olson 1935), though caution must be observed in drawing conclusions on the frequency of infection from serological results alone. The disease can be reproduced by feeding and by parenteral inoculation, and may be characterized by fever of an undulating type. In both naturally and experimentally infected animals the organism may sometimes be demonstrated in the blood stream or urine (v.d. Hoeden 1932*c*, Thomsen 1932*b*, Feldman, Bollman, and Olson 1935, Olson and Feldman 1936). Most cases appear to be due to *Br. abortus*, but at least one *suis* infection has been described (Planz and Huddleson 1931). Though dogs probably play little part in the general spread of *Brucella* infection, their possible rôle as carriers must be considered in attempts to eradicate the disease from cattle or other animals.

Little is known about the incidence of *Brucella* infection in *cats*, though considering their habit of drinking raw cows' milk it is difficult to believe that they are not frequently infected. Experimentally, both *Br. abortus* and *Br. melitensis* may give rise to a severe disease with lesions in the joints and internal organs (Makkawejsky and Karkadinowskaja 1932).

Fowls.—The frequency of *Brucella* infection in fowls is still under discussion. Emmel and Huddleson (1929, 1930) brought evidence to suggest that the disease was very common in the United States, but their observations have not been altogether confirmed by subsequent workers (McNutt and Purwin 1930, v. Roekel *et al.* 1932). It is noteworthy that their conclusions were based on the presence of agglutinins in the blood. The isolation of the organisms from the tissues of naturally infected birds seems to have been very rarely accomplished. Beller and Stockmayer (1933*a*) have shown that normal fowls frequently have agglutinins in their blood, and that no attention can be paid to a titre of less than 1/150 or 1/200. Most workers have found that experimental inoculation of fowls gives rise to an inapparent infection, having little or no effect on the health or egg-laying capacity of the birds (see McNutt and Purwin 1930, 1932, v. Roekel *et al.* 1932, Lombardo 1932, Beller and Stockmayer 1933*a*, *b*, and Chapter 34). The natural infection seems to be more of epidemiological than clinical interest, though further observations are required, particularly to find out whether fowls may transmit infection to cattle.

Rats.—Little is known of the occurrence of natural infection in wild rodents, though, in view of the possible part played by these animals in the spread of infection among cattle, knowledge is urgently required. Karkadinovsky (1936) examined 34 wild grey rats on three farms infected with contagious abortion, and isolated *Br. abortus* from 11 of them. Most of the positive cultures were from the spleen and liver, but in two of the animals the blood was also found to be infected. Bosworth (1940), on the other hand, who examined 167 rats caught on farms where the disease was prevalent, found only one harbouring *Br. abortus*. The observations of Bosworth (1937) and of Sandholm (1938) show that rats can be infected by feeding, and that the organisms can be excreted for a short time in the faeces and urine, but that on the whole the animals are relatively resistant and that tissue lesions seldom occur.

Infectious Abortion in Cattle and Sheep due to *Vibrio fetus*

In 1913 M'Fadyean and Stockman (Report 1913) described an enzootic abortion of sheep due to a spirillar organism, which was later called *Vibrio fetus* by Smith (1918). In this country, vibrionic abortion appears mainly to affect sheep, though the disease has been observed in cattle; but in the United States it is responsible for a considerable proportion of cases in cattle. Smith (1919) found, for example, in 109 cases of abortion in which a relatively thorough examination of the fœtus and membranes was made, that 62 were due to *Br. abortus*, 26 to *V. fetus*, 2 to *C. pyogenes*, while in the remaining 19 no organisms were isolated or mixed cultures were obtained. The general epidemiology and bacteriology of vibrionic abortion are similar to those already described for the more common type of abortion. Thus infection appears to occur by feeding, and possibly by vaginal contamination: the vibrios are found in large numbers in the uterine exudate, in the placenta, and in the contents of the fœtal stomach: agglutinins are present in the serum of infected animals, active up to a dilution of 1/610 or even higher (Smith *et al.* 1920): and pregnant cows can be infected by the mouth, though more certainly by intravenous inoculation.

An organism similar in many respects to *V. fetus*, and called *V. jejuni*, appears to be responsible for *autumn diarrhœa in cattle* in the United States (see Jones and Little 1931, Jones, Orcutt, and Little 1931, and Chapter 22).

TULARÆMIA

Synonyms: Deer-fly fever, Pahvant Valley fever, Ohara's disease.

In 1911 McCoy described a plague-like disease amongst the ground-squirrels (*Citellus beecheyi* Richardson) of California. The following year McCoy and Chapin (1912) isolated the causative organism—a very tiny Gram-negative bacillus—from naturally infected animals, and reproduced the disease with pure cultures in guinea-pigs. They named it *Bact. tularense*—from Tulare, the county in which the disease was first observed. (This organism probably belongs to the *Brucella* group, see Chapter 34.) In 1921 the disease caused by this organism came to be known as tularæmia. It is apparently widespread amongst rodents in America, particularly in the Western States; ground-squirrels, hares and jack-

rabbits are the animals chiefly infected. The lesions found in animals dead of the disease are similar to those of plague; there is a bubo, generally in the cervical, axillary, or inguinal region, containing dry, yellowish, caseous material; the spleen is greatly enlarged, very dark in colour, and contains yellowish-white, discrete, caseous granules up to 1 mm. in diameter, projecting slightly above the surface; there are numerous granules in the liver; the lungs are rarely affected; the organisms are present in enormous numbers in the spleen, in smaller numbers in the liver, bubo, and heart's blood (McCoy and Chapin 1912). Experimentally the disease can be reproduced in ground-squirrels, gophers, guinea-pigs, rabbits, mice, and monkeys; rats are more resistant; cats, dogs, and pigeons appear to be immune. Feeding, nasal instillation, cutaneous, subcutaneous, intraperitoneal, and conjunctival injection are all successful (see Chapter 34.) The disease appears to be spread by blood-sucking insects, especially ticks (McCoy and Chapin 1912, Francis 1921, Francis and Lake 1922, Parker *et al.* 1924, 1929). According to Parker and Spencer (1926*b*) the organism may be transmitted from infected female ticks to their progeny; if this is true, it is one of the few examples known of the hereditary transmission of a bacterium by insects.

The first case of the disease in man was reported in 1914 by Wherry and Lamb in the United States. From 1924 to 1937 inclusive, 8,022 cases of infection with 358 deaths were recognized (Olson 1938), though there is reason to believe that numerous other cases occurred that were not diagnosed (see Francis 1921, Culpepper 1926, Dieter 1926, Freese *et al.* 1926, Lavan 1926, Maclachlan *et al.* 1926, Parker and Francis 1926, Cumming 1930). The disease has been met with in Japan, where it is known as Ohara's disease (see Ohara 1930), in Norway (see Wefring 1930), in Soviet Russia (see Doubrowinsky 1930, Karpoff and Antonoff 1936), in Sweden (Olin 1938*a*, *b*), in Austria and Czechoslovakia (Drbohlav 1937), and in Turkey (Arar 1937). Cases are mainly sporadic, but occasional outbreaks have been reported. The case mortality is about 5 per cent.

Mode of Infection.—Infection of man is most commonly due to the handling of infected rodents, and occurs either directly through contamination of the hands with the tissues or indirectly through the bites of parasites. In the United States about 90 per cent. of cases are traced to contact with wild rabbits and hares (Cumming 1937), but in some instances infection is transmitted by wood ticks (*Dermacentor andersoni* and *D. variabilis*) and deer flies (*Chrysops discalis*) (see Francis 1921, Parker and Francis 1926, Hillman and Morgan 1937, Olson 1938).

In Norway and Sweden infection has been traced to hares (Thjøtta 1930, 1931*b*, Olin 1938*b*), and in Soviet Russia to water rats (Sarchi 1929, 1930), and to susliks (Tumansky and Kolesnikova 1935). The "lemming fever" of Norway, which follows the consumption of drinking water polluted by the bodies and excreta of the lemming, is thought to be related to tularæmia (Thjøtta 1931*a*). Some cases in man have been traced to contact with sheep, which may occasionally suffer from tularæmia (Parker and Dade 1929, Philip and Jellison 1935). Case-to-case infection is said to be rare. The incidence of the disease is mainly on those classes of the population who are brought into contact with infected animals, such as butchers, poultry-men, and trappers. Laboratory workers are often attacked (Parker and Spencer 1926*a*). Indeed there is probably no other organism that is so dangerous to work with in the laboratory. Unless scrupulous care is taken to avoid infection of the skin, nose, and conjunctiva, from fluid cultures and inoculated animals, the disease will almost certainly be contracted.

The way in which the organism enters the body is not known, but the evidence suggests that the site of infection is generally the skin of the fingers or the conjunctiva. It is known that in guinea-pigs the organism can pass through the intact skin (Lake and Francis 1922), and there is reason to believe that it may do so in human beings, though infection is probably aided by the presence of small wounds and abrasions. The incubation period of the disease is generally stated to be about 3 days. In the usual glandular type of the disease, seen in butchers and poultry-men, after an acute onset with headache, rigors, pains and fever, a papule appears, generally on the back of the finger, which breaks down and leaves a ragged ulcer. The epitrochlear and axillary glands swell and become painful; they often break down and discharge purulent material. Fever is common for the first 2 or 3 weeks. Convalescence is very slow. When the organism gains entrance through the conjunctiva, ulcers may form on the inner surface of the eyelids, followed by swelling and tenderness of the preauricular and cervical glands. In the typhoid type of the disease there are no localizing symptoms. It is this type that is usually seen in laboratory workers (Lake and Francis 1922). Death, when it occurs, is commonest during the 3rd week. In those patients who have been examined at post mortem, multiple small abscesses in the regional lymphatic glands, the spleen, liver, and lungs have often been found (see Francis and Callender 1927, Foulger *et al.* 1932).

Diagnosis, Prevention and Treatment.—Diagnosis in animals is best made by macroscopic, microscopic, cultural, and pathogenicity tests. In the differential diagnosis from plague, account should be taken of the absence of pus at the site of infection, the greater variability in size of the granules in the spleen, the rarity with which the lungs are affected, and the failure of the organism to develop on ordinary media. In man, discharge from the local lesions or glands should be cultivated directly on to special media (see Shaw and Hunnicutt 1930), and injected into guinea-pigs (Francis 1923). The agglutination test is of special value (Francis and Evans 1926). It becomes positive, as a rule, during the 2nd week of the disease, and reaches its maximum between the 4th and 8th weeks. The titre varies from about 1/160 to 1/5,000. Sera agglutinating *Br. tularensis* at 1/320 or higher often act on *Br. abortus* as well. In some cases the two organisms may be agglutinated to the same degree. Agglutinins to *Br. tularensis* persist in low titre for years after the attack (Ransmeier and Ewing 1941). Curiously enough the organism does not often appear to be present in the blood (Lake and Francis 1922). Intradermal diagnostic tests have been described (Foshay 1932, 1936).

In animal experiments no cross-reactions are said to occur between "protein nucleate" solutions prepared from *Br. tularensis* and from the other three members of the *Brucella* group (Pennell and Huddleson 1941).

Prevention of the disease lies in avoiding contact of the skin with potentially infected material, such as wild rabbits and hares. Immunity after an attack is lasting. Persons exposed to risk of infection may be vaccinated prophylactically. Foshay and his colleagues (1942) recommend three doses of a vaccine made from organisms killed with nitrous acid, followed by annual revaccination. Immune serum prepared by the inoculation of a goat has been tried on a small scale for the treatment of patients suffering from the disease (Foshay 1934).

CHAPTER 76

ANTHRAX

History

ANTHRAX is a disease that has been known from antiquity. In earlier days, however, it was not clearly separated from other affections closely simulating it. Maret (1752) and Fournier (1769) defined the clinical type of malignant pustule in man, and Chabert (1780) gave a clear description of anthrax in animals. In 1823 Barthelémy showed that it was transmissible by inoculation. Rayer (1850) described small, non-motile, filiform bodies in the blood of sheep dead of the disease, and confirmed its transmissibility by inoculation. (For references see Hutyra and Marek 1922.) In a series of papers, Davaine (1863*a*, *b*, *c*, 1864) showed that anthrax could be transmitted to sheep, horses, cattle, guinea-pigs, and mice, by the subcutaneous inoculation of infected but not of normal blood; that in such animals the bacilli did not appear in the blood till 4 or 5 hours before death; that in the blood they increased rapidly in numbers, and became filamentous; and that after death they disappeared as soon as putrefaction commenced. He showed, moreover, that the blood of an infected animal, previous to its invasion with the bacilli, was non-infective, but that after invasion it was capable of conveying the disease; that animals fed on infected viscera frequently became infected, but that animals fed on the putrefying organs of non-infected animals did not do so; and that after death from anthrax the spleen, liver, kidneys, lungs, blood, and, to a less extent, other organs contained the bacilli in large numbers. In the same year, Tiegel and Klebs (see Koch 1881) showed that anthrax blood, if filtered through a clay candle, was deprived of its infectivity; the filtrate was innocuous to animals, but the deposit on the filter remained active. These observations showed, as conclusively as could be expected in the absence of cultivation, that anthrax was caused by a living organism that multiplied in the body, invaded the blood stream, and produced death by septicæmia. To this organism Davaine gave the name of *Bactéridie*—a name by which it is still known among French writers. Subsequently Davaine and Raimbert (1864) found the same organism in a malignant pustule in man, thus demonstrating the ætiological identity of the disease in man and animals.

The final proof of the causative rôle of *B. anthracis* was produced by Koch (1877), who, in a classic masterpiece, which brought him suddenly into fame, gave a full account of the organism, described its formation of resistant spores, its cultivation *in vitro*, the reproduction of the disease by injection of pure cultures, and the recovery of the organism from the animals at necropsy.

The subsequent history of anthrax is largely connected with attempts at

immunization, first made by Toussaint, and later with more success by Pasteur, by Sclavo, and by Sobernheim (see section on Vaccination).

Epidemiology

Anthrax in Animals.—Anthrax is primarily a disease of animals, from which man is secondarily infected. To understand the epidemiology of the disease in man, it is therefore necessary to consider first its incidence amongst animals.

Anthrax is a widespread disease occurring in nearly every country in the world. There are areas, such as the Beauce, Champagne and Auvergne in France, Eastern Prussia, the plains of the Danube, and parts of Siberia and Asia Minor in which it is specially prevalent, and from which it never dies out. As a rule, it is commoner in swampy, low-lying districts with warm, loose, moist soils, and in the great deltas, such as those of the Mississippi and the Brahmaputra. In warm countries its maximum incidence is in the months of June, July, August, and September, but in colder countries, such as Great Britain, the disease is commoner during the winter months. The most susceptible animals are the herbivora. Cattle, sheep, pigs, horses, and goats are the chief sufferers, but the disease may occur in dogs, cats, camels, buffaloes, deer, and even in beasts of prey. Algerian sheep are highly resistant (Chauveau 1880*a*). In Europe the incidence is usually greater among cattle than among sheep, but in Australia and South America sheep are more frequently affected.

Since the Anthrax Order of 1910 came into force, the number of outbreaks in Great Britain has varied between about 400 and 700 a year (Reports 1914–1937). In the year 1937 there were 743 outbreaks affecting 820 cattle, 30 swine, 13 horses, 1 sheep, and 15 other animals. Since the total number of animals affected was only 879, it follows that rarely more than 1 or 2 animals were concerned in any one outbreak. This is very different from the type of outbreak that still occurs in many continental areas, where whole herds may be decimated. A reason for this difference will be suggested under the section dealing with the mode of spread of the disease. Table 165 gives an idea of the frequency of the disease in different parts of the globe (Page 1909).

TABLE 165

SHOWING THE AVERAGE ANNUAL NUMBER OF CASES OF ANTHRAX AMONGST ALL ANIMALS BETWEEN 1902 AND 1906.

United Kingdom	1,263
Italy	4,585
Germany	5,559
British India	29,398
European Russia, Finland and N. Caucasus	46,169

As a rule, anthrax in animals takes the form of a septicæmia, varying from a sudden apoplectic attack with death occurring in a few minutes after the appearance of the first symptoms, to a subacute type, manifested by fever, and frequently by intestinal disturbances, terminating fatally after about a week. In cattle and horses, circumscribed cutaneous swellings or carbuncles may sometimes appear, not unlike the malignant pustule of man; in swine and dogs, localization is common on the mucosæ, particularly those of the pharynx and larynx. These

forms with local manifestations are rarely so fatal as the general septicæmic disease.

Mode of Infection and Spread.—Anthrax is rarely spread directly from animal to animal. Infection generally occurs by the alimentary tract from ingestion of infected food. During the last stages of the disease in animals, the bacilli are excreted in the urine, fæces, and saliva. At the time of death and for some time afterwards, bloody infected fluid exudes from the openings of the body, and soils the neighbouring ground. The bacilli, which in the blood are invariably in the vegetative form, after being voided from the body soon produce spores under the influence of a suitable temperature and free access of oxygen. These spores are extremely resistant to inimical agencies and may remain alive on the surface of the ground for as long as 12 years (Pasteur 1881*a*). Cattle or sheep feeding on this ground are liable to be infected; the spores are taken in by the mouth; they probably pass through the stomach unharmed, multiply in the small intestine, invade the mucosa, and reach the blood stream.

This view, which was largely developed by Koch (1881) differed in some respects from that put forward by Pasteur (1880), who maintained that infection occurred through the mouth and pharynx. As evidence of this, he showed that if sheep were fed on spores, a certain proportion died of anthrax; but that if to the infected food were added prickly substances, such as the pointed extremities of dried thistle leaves or barley spikes, which were able to cause erosions of the pharyngeal mucosa, the mortality amongst the sheep was increased. Pasteur, moreover, maintained that earth-worms played an important part in the actual contamination of the ground. He supposed that, when an animal was buried, the bacilli exuding from the openings of the body developed into spores, which were then brought by earth-worms to the surface of the soil, where they were deposited as casts. It is doubtful what importance is to be attributed to this view. Koch (1881), who examined a number of earth-worms placed in artificially infected soil, found that they rarely became infected; and he brought indirect evidence to suggest that their rôle in the contamination of the ground was negligible in comparison with that caused by the exudation of infected body fluids from animals just before or after death.

The view that the infection of animals occurs chiefly by feeding on contaminated pasture land affords a possible explanation of the greater prevalence of anthrax in low-lying, marshy areas, and by the banks of streams, where grasses and decaying vegetable materials are abundant on which the bacillus may grow; of the rise in incidence as soon as the weather becomes warm; and of the absence of an æstival prevalence of the disease in cold countries. It is, however, by no means clear that the anthrax bacillus can multiply on the surface of the soil under natural conditions, and the view is held by some workers that the organism is an obligatory parasite (see Minett and Dhanda 1941).

In Great Britain, as already stated, the greatest number of cases occurs during the winter months. This fact alone is sufficient to suggest that the mode of infection is different from that in warmer climates. Though occasional infection may occur by contamination of the ground with the effluents from tannery and other industrial works, M'Fadyean (1903*b*) has brought evidence to show that soil infection plays little part in the spread of the disease in this country; and that the majority of cases are traceable to imported food-stuffs. The evidence for this is, briefly, that anthrax occurs sporadically, not epidemically, as might be expected if the soil was the main source of infection; that the disease is commonest during the winter months, when artificial food-stuffs are most used; that it is more frequent amongst cattle, which receive artificial food-stuffs, than amongst sheep, which do not; that 80 per cent. of outbreaks (Stockman 1911)

occur on previously uninfected farms; and that in most outbreaks there is a history of artificial feeding. (See also Jackson 1930.) This evidence, almost entirely circumstantial, has been supplemented by work abroad. In Germany in 1914, there were 7,181 cases of anthrax in animals; in 1919 there were only 743. This tenfold decrease is attributed to the cessation, during the war, of the importation of artificial food-stuffs (Poppe 1922). That such food-stuffs may actually contain anthrax spores has been demonstrated for bone, fish and maize meal, for barley, and for oil-cake.

Another method of infection that may occur, though less commonly, is by flies. *Stomoxys calcitrans*, horse flies, and mosquitoes, for example, have been shown experimentally to convey anthrax (Poppe 1922). The transmission is mechanical (Morris 1918); there is no development of the bacilli in the insect's body.

Summarizing, we may say that in warm countries animals are infected chiefly by contaminated pasturage, less often by biting flies; that in cold countries the chief mode of infection is apparently by artificial food-stuffs; and that the most frequent mode of infection appears to be through the alimentary tract. This last conclusion has been challenged by Besredka (1921) who believes that infection occurs through the skin (see Chapter 53), and by Sanarelli (1925) and by Rovida and Schwarz (1928*a*, *b*), who were unable to demonstrate in laboratory animals the passage of anthrax bacilli through the intact intestinal mucosa.

Excluding very mild and latent cases, the mortality in animals seems to vary between 75 and 100 per cent.

Anthrax in Man.—Anthrax in man may be divided into (1) the non-industrial type, affecting shepherds, farmers, veterinary surgeons, knackers, butchers, pathologists, and others coming into close contact with infected animals; and (2) the industrial type, arising from the manipulation of wool, animal hair and bristles, hides and skins, or occurring in other industries such as those dealing with harness, furniture, cutlery, boots, manure, rag-sorting, horn, or grain porterage. The epidemiology of these two types is so different that they must be treated separately.

The first type, which takes the form of malignant pustule, is due to contamination of the skin with material from infected animals. It is particularly common, therefore, in countries having a high incidence of anthrax amongst animals, and is relatively uncommon in countries, such as Great Britain, where the incidence amongst animals is low. Moreover, there is a close correlation between the seasonal incidence of anthrax in animals and in human beings. This is well seen in southern Italy, where the number of cases in man rises almost simultaneously during the summer months with the increased prevalence amongst animals (Page 1909), and in Bulgaria (Koschucharoff 1938). In the United States agricultural anthrax is on the increase (Report 1934–35).

The second type of anthrax, which may take the form of malignant pustule or pulmonary disease, is dependent on infection acquired during the industrial treatment of animal products, and shows no special seasonal incidence. For convenience of reporting, the cases in this country are divided into 5 groups (Table 166).

Anthrax is a relatively uncommon disease in Great Britain and America. The total number of cases in England and Wales for the twelve years 1913 to 1924 was 743, of which 109, or 14·7 per cent., were fatal. During the twelve years 1927 to 1938 there were only 79 deaths. In the United States during the five years 1934 to 1938 there were 322 cases with 50 deaths, that is, a case mortality of 15·5 per cent. (Reports 1934–38.)

TABLE 166

INCIDENCE OF INDUSTRIAL ANTHRAX IN GREAT BRITAIN.[1]

Year.	Wool.	Horsehair.	Hides and Skins.	Other Industries.	Dock Labourers.	Total.
1913 . . .	43 (5)	5 (1)	19 (2)	3	3	73 (8)
1914 . . .	29 (5)	5	15	6 (1)	7 (2)	62 (8)
1915 . . .	26 (2)	2	18 (3)	3 (1)	0	49 (6)
1916 . . .	80 (12)	6 (3)	18 (3)	2	2 (1)	108 (19)
1917 . . .	65 (11)	1	29 (2)	4 (1)	3 (1)	102 (15)
1918 . . .	49 (4)	4 (3)	14 (1)	1	3	71 (7)
1919 . . .	34 (5)	3 (1)	16 (1)	4 (2)	3 (2)	60 (11)
1920 . . .	25 (7)	5 (1)	17 (3)	1	4 (1)	52 (12)
1921 . . .	11 (3)	4 (1)	8 (1)	2 (1)	0	25 (6)
1922 . . .	19 (3)	9 (1)	16 (1)	1	1	46 (5)
1923 . . .	14 (1)	9 (2)	22 (1)	1 (1)	4 (3)	50 (8)
1924 . . .	19 (1)	4 (1)	16 (2)	4	2	45 (4)
Total . . .	414 (59)	57 (13)	208 (20)	32 (7)	32 (10)	743 (109)

The figures in brackets indicate deaths.

[1] For this Table, we are indebted to the kindness of Dr. S. A. Henry, H.M. Medical Inspector of Factories.

In the woollen industries, anthrax occurs almost entirely round the Bradford district of the West Riding and in Worcestershire; the other centres are exempt. This can be explained by the fact that the dangerous classes of raw wool from Asia Minor and Persia are used in these districts. Amongst those engaged in the horsehair industry, the maximum incidence falls on those using the dangerous classes of hair from China, Russia, and Siberia. Among the dock porters, the incidence falls chiefly on those working in the ports of London and Liverpool (Legge 1905). (For incidence of human anthrax in Germany, Austria, and the United States during recent years, see Report 1934 35.)

In all but the woollen industry, the type of anthrax contracted is the malignant pustule. As infection occurs from contamination of the skin with the infected animal products, it is natural to expect that the uncovered parts of the body will suffer most severely. Legge (1934) gives the following table (Table 167), showing the site of the pustule:

TABLE 167

LOCATION OF MALIGNANT PUSTULE.

Situation.	Number.	Per cent.
Head and face	418	44·6
Neck	292	31·2
Upper extremity . . .	191	20·4
Lower extremity . . .	18	1·9
Trunk	18	1·9
Total	937	100·0

The site of the lesion varies, moreover, with the nature of the industry. Hide porters, for example, are frequently infected on the back of the neck, which is more open than other parts to excoriation. In butchers and others who have to handle

carcasses, the arm is often affected. The face and neck are prone to attack in those using infected shaving brushes (Vincent 1922, Report 1921), and so on. In the woollen industries, infection occurs during the processes of sorting and combing. The worker inhales a large quantity of dust containing anthrax spores, and is hence liable to the pulmonary type of anthrax. Fifty years ago pulmonary infection was commoner than the malignant pustule, but improvements in factory legislation have diminished this type considerably.

The various products that are liable to give rise to anthrax in man come from regions where the disease is common in animals; their danger is in proportion to the chance of their being infected. Hides and wool are frequently contaminated with blood; horse hair and hog bristles are contaminated from various sources.

Owing to their greater exposure, anthrax is more common amongst men than women, but the disease is more fatal in women. The case mortality of cutaneous anthrax depends largely upon the site of infection and the day on which treatment is started. According to Legge (1934) it ranges from about 3 per cent. on the forehead to about 24 per cent. on the neck. Eurich (1930) estimates the usual case mortality at 5 to 15 per cent. Respiratory and alimentary anthrax are almost invariably fatal.

Apart from the methods already mentioned, anthrax may be conveyed to man by the bites of insects that have just fed on the carcass of an infected animal. Contact infection in human beings is uncommon. Occasionally infection may occur by the food, and give rise to the intestinal form. The bacilli are destroyed by the gastric juice, but the spores escape and multiply in the intestine. Experimental evidence, based on findings in laboratory animals, suggests that for this mode of infection to occur in man, large numbers of spores must be present in the food. It is worth while mentioning that the milk of animals dying or just dead of the disease may contain the bacilli (M'Fadyean 1909); chances of infection by this method must, in this country at least, be rare.

It will be seen, therefore, that man is infected with anthrax only as a result of his dealings with animals or with animal products. Methods of prevention must be founded on an understanding of this fact.

Apart from malignant pustule, and the less common respiratory and intestinal forms of the disease in man, meningitis is not infrequently caused by the anthrax bacillus.

Bacteriology of Anthrax in Man and Animals.

Anthrax is a disease that, when fatal, invariably terminates in septicæmia. Whatever form the disease takes—the malignant pustule, respiratory, or intestinal—it is characterized by a primary local proliferation of the bacilli, with the formation of local lesions. The fate of the animal rests on the result of this local attack; if it is resisted by the phagocytes and other defences of the body, recovery rapidly occurs; if the bacilli prove too virulent, they invade the blood stream, and multiply abundantly. This invasion occurs late—generally not more than a few hours before death—and is accompanied by severe toxic manifestations. It is characteristic of anthrax that the bacilli remain confined almost entirely to the blood vessels; they are found in maximum numbers in the capillaries of the liver, lung, kidney, spleen, intestine, and stomach, in smaller numbers in those of the brain, skin and muscle. Their distribution varies, however, with the animal attacked. In the blood of mice or rabbits, for example, there are few bacilli to be

found; in guinea-pigs there may be more bacilli than red blood corpuscles. In the larger animals they are usually plentiful, but pigs and horses may die before the organisms have proliferated sufficiently to be detected microscopically (Stockman 1911).

In man, the malignant pustule starts as a small area of inflammation. It increases in size at a varying rate. Coagulation necrosis of the centre occurs, leading to the formation of a brown, purplish or black eschar surrounded by an intermediate zone of vesicles filled with clear yellow or sanious fluid, and an outer zone of widespread œdema and induration. There is no true pus and relatively little pain (Hodgson 1941). The bacilli are most abundant immediately below the central necrotic area. Invasion of the blood stream may occur, but the number of organisms is seldom as great as in the larger animals (Eurich 1930).

Experimental Production of Anthrax in Animals.—Under natural conditions, the disease is confined chiefly to the herbivora and to man, but occasionally other animals are attacked. Experimentally the disease can be reproduced in the herbivora, rodents, and the omnivora; birds, with the exception of sparrows, and to a less extent hens, ducks, and pigeons, are resistant. Reptiles and fish are insusceptible to infection.

Most of the early experiments on the larger animals were performed with the infected blood of other animals, and it was found that for transmission to be successful certain precautions had to be taken. Putrid blood, for example, often proved non-infective; as did blood that had been rapidly dried after removal from the body. On the other hand, blood or tissues that had been dried slowly were found to retain their infectivity for at least 4 years (Koch 1877). The occurrence of these anomalies was shown by Koch (1877) to be dependent on the presence or absence of spore formation. He found that whenever the bacilli had formed spores, and these spores were capable of being cultivated *in vitro*, the material containing them was infective to animals. The blood of a fœtus removed from a cow that had succumbed to anthrax proved innocuous, showing that the organisms had not passed the placental filter.

FIG. 292.—*Bacillus anthracis.*
Smear from spleen of experimentally infected guinea-pig, showing the bacilli in large numbers (× 1000).

The disease produced in the larger animals is similar to that occurring naturally. Certain points, however, deserve notice. Sheep can be infected equally well by whatever route the organism is introduced. Cattle, on the other hand, are resistant to subcutaneous inoculation, but are easily infected by the alimentary route (Koch *et al.* 1884). Subcutaneous inoculation in cattle may give rise to a severe spreading œdema, but never to a true malignant pustule; moreover, the animal generally recovers. Chauveau (1880*b*) found that the dose was of considerable importance. Large doses injected into sheep caused a 100 per cent. mortality; smaller doses caused a 50 per cent. mortality; whereas tiny doses of about 50–100

organisms were well supported, and were followed by immunity. In feeding experiments, the dose is very important. Oppermann (1906) was unable to infect sheep by this method with less than 100,000 spores. Koch, Gaffky and Loeffler (1884) found that sheep could be infected by feeding as certainly as by subcutaneous injection, provided large numbers of spores were given; with small numbers the results were irregular or completely negative. (For pathogenicity to small animals see p. 844.)

Diagnosis.

In animals suspected of having died of anthrax, it is important that a post-mortem examination should not be made, otherwise blood will be spilt on the neighbouring ground and will provide a source of infection for other beasts. In this country such post-mortems are now illegal. It is sufficient in cattle and sheep to cut off an ear and send it to the laboratory; or alternatively a swab should be soaked in the blood and several blood-films should be prepared for examination. In pigs and horses, however, as death may occur in the early stages of septicæmia when very few organisms are present in the blood, it is advisable to excise a superficial lymphatic gland, and to make smears of any œdematous fluid that may be present. Malignant pustule can often be diagnosed by bacteriological methods early in the disease, but anthrax of the respiratory and alimentary systems can rarely be diagnosed till late.

Microscopical Examination.—Microscopical examination of fresh material is generally sufficient to enable a provisional diagnosis to be made.

The blood or fluid should be spread on a slide and stained without fixation by Gram's method. A rather thicker film should be fixed imperfectly by three passages through the flame, and after being allowed to cool, stained for a few seconds with 1 per cent. aqueous methylene blue, washed thoroughly in water, and dried in air. By Gram's method the bacilli are stained violet; by the second method—described independently by Heim (1901) and M'Fadyean (1903*a*, *c*, 1904)—they are stained sky blue, but are surrounded by a deposit of granular or amorphous material, coloured reddish-purple, probably representing the debris of the imperfectly fixed capsules. The bacilli are arranged singly or in pairs; usually they are about 4–6 μ long, but at times filamentous forms may be seen. They may be closely simulated by *Cl. welchii*, a large Gram-positive capsulated anaerobic bacillus which may invade the blood stream in certain conditions; the exclusion of this organism must rest on cultural examination. Their number

FIG. 293.—*Bacillus anthracis.*

Smear from a malignant pustule in man, showing the bacilli in small numbers (× 1000).

varies greatly. In the fluid taken from a malignant pustule in man, they may be so few as to escape observation; but if sections are made of a portion of excised tissue, embedded in paraffin, and stained by Gram, they can generally be found. Not too much attention should be paid to negative findings.

Cultural Examination.—Where possible, fresh material should be used. The blood or tissue juice may be taken on a swab, but unless it is to be examined at once it is better to collect it on a sterile thread or fragment of earthenware, or a piece of gypsum that has been soaked in broth and subsequently sterilized (Strassburg method). The drying of the material prevents the destruction of the bacilli by the bactericidal power of the serum (Eurich 1933), facilitates their rapid sporing, and prevents the growth of other organisms. Cultures are put up in the usual way on to agar plates and into broth, and the resulting growth carefully studied. It is important not to confuse *B. anthracis* with other members of the aerobic spore-bearing group. To avoid this, it should be remembered that the anthrax bacillus is non-motile, and liquefies gelatin slowly, whereas most of the other members are motile, and liquefy gelatin rapidly. (For the further differentiation of *B. anthracis* from anthrax-like bacilli, see Chapter 35.)

If wool or hair is to be examined, it should be soaked in a weak solution of KOH, incubated for some hours, teased out, heated at 80° C. for 2 minutes, and seeded into 2 per cent. peptone agar, which is then poured into Petri dishes. Particular attention should be paid to the deep colonies, which, in cultures less than 24 hours old, have a characteristic opaque white filamentous appearance with sometimes a nebula at one end (Eurich 1912).

Pathogenicity Tests.—If possible, these should be carried out with the pure cultures that have been isolated. If the original material is used, particularly if this is old, putrid, or contaminated, the animal may die of infection with some organism other than *B. anthracis*. As a routine, the best animals to employ are the mouse and the guinea-pig.

About 0·5 ml. of a 24-hours' broth culture should be injected subcutaneously into the thigh. Death generally occurs within 2 to 3 days; post mortem, there is a hæmorrhagic gelatinous exudate at the site of inoculation, and a large, congested, dark-red spleen (see Chapter 35); microscopically, the bacilli are found in the blood and in smears made from the viscera (Fig. 292, p. 1736). Cultures should be put up for confirmation.

If the only available material is putrid, it is well to inoculate 3 or 4 mice by scratching the skin with a needle dipped in the fluid. As the anthrax bacillus can gain entrance through the abraded skin more easily than other organisms with which it is liable to be contaminated, death of one or more of the mice will probably occur from a pure anthracæmia. This method, first described by Koch, Gaffky and Loeffler (1884), is a good example of the method of purification of cultures by animal inoculation (see Chapter 12).

Wool, hair, or other industrial material should be suspended in water—if necessary after alkaline treatment in the way described under cultural examination—the suspension should be centrifuged, and the deposit inoculated into 2 or 3 guinea-pigs. The animal test is more delicate than the plate method. Using it, Glynn and Lewis (1912), to whom reference should be made for fuller particulars, isolated anthrax spores from 21·3 per cent. of 141 samples of industrial material—mainly hides, wool, hair and bones—supposed to have produced anthrax in Liverpool.

Serological Diagnosis.—Neither the agglutination nor the complement-fixation test is of value for diagnosis. There is one test, however, depending on the presence in infected animal tissues of a substance—a precipitinogen—that reacts with a suitable immune serum to form a precipitate, which has been found of great value; this is Ascoli's thermoprecipitin reaction.

Ascoli (1911) worked with saline extracts of tissues at room temperature, but he found that, for practical purposes, time could be saved by extraction at 100° C. For diagnosis,

the organs or blood of the suspected animal are ground up and suspended in saline, boiled for 5 minutes, filtered through paper and allowed to cool. Of this extract, 0·5 ml. is run very carefully on to the surface of a similar quantity of immune serum in a small tube. Within 15 minutes at room temperature, a definite ring-like precipitate forms at the junction of the two fluids. It is necessary to control the test very carefully with a known anthrax extract and with a normal serum. The method is a delicate one, and may give a positive result with material that has been kept for 2 years or more. A modification of the test was described more recently by Standfusz and Schnauder (1925), and an improved method of preparing high-titre precipitating sera by Rosenberg and Romanow (1929). The precipitable substance in the tissues is derived both from the capsular protein antigen and the somatic polysaccharide antigen. According to Tomcsik and Szongott (1933), most commercial sera contain precipitins only for the polysaccharide. Since there is more protein than polysaccharide antigen in the tissues (Tomcsik and Bodon 1934), it would probably be better to use a serum containing precipitins for both components (see also Iványovics 1939).

Natural Immunity.

The investigation of the natural resistance of certain animals to anthrax played a prominent part in the controversy between the cellular and humoral schools of immunity, in the early days of bacteriology. Without attempting to adduce all the evidence that was brought forward during this controversy, we shall merely draw attention to some of the salient points. Von Behring (for references see Chapter 52) found that the blood serum of the rat—an animal that is fairly resistant to anthrax—possessed a remarkable destructive action on the bacillus and he was led to conclude that the immunity of this animal was dependent on the bactericidal content of its serum (see p. 1173). On the other hand, Metchnikoff and his co-workers stated that, though the blood serum of the rat is bactericidal *in vitro* to the anthrax bacillus, the blood plasma *in vitro* does not possess this action. Furthermore, the spores are able to develop in the body of the rat, and to cause a symptomless infection (Kritschewski and Messik 1930); their further proliferation is restrained by the attack of the phagocytes, which ingest and destroy them. The serum of the rabbit, like that of the rat, has a bactericidal effect on the anthrax bacillus, yet the rabbit is susceptible to experimental inoculation with this organism.

The dog presents another interesting example. When young it is fairly susceptible; when older it is more resistant to experimental injection. Nuttall (1888) found that the defibrinated blood of the dog readily destroyed the bacilli; Metchnikoff was unable to confirm this, but demonstrated a close correlation between the phagocytic activity of the leucocytes and the resistance of the animal. Methods such as removal of the spleen, or intravenous injection of fine wood charcoal, which served to divert the leucocytes, destroyed this resistance.

Pasteur, Joubert and Chamberland (1878) found that the natural resistance of fowls to injection with anthrax could be destroyed by immersing them up to the thighs in cold water; they concluded that the immunity of these birds depended on their high normal temperature (41–42° C.), which interfered with the development of the bacillus. That this explanation was incorrect was shown by Wagner (1890), who found that the bacillus developed readily in the blood and blood serum of fowls outside the body, even at a temperature of 43° C. Further experiments led to the conclusion that the immersion in cold water served to lower the phagocytic response, and thus allow the bacilli to proliferate. We may also quote the experiments of Charrin and Roger (1890), who stated that the natural resistance of rats could be broken down by excessive exercise, and of Preisz (1909), who found that frogs were resistant if kept at 18° C. but not at 30° C.

Weyl (1892) found that anthrax-infected threads, planted in the subcutaneous tissues of hens or pigeons, were rendered avirulent for mice in 4 days; he satisfied himself that the bacilli were killed by the phagocytes as soon as the spores germinated.

Chauveau (1880c) stated that if anthrax bacilli were injected intravenously into vaccinated animals, the bacilli rapidly disappeared from the circulation, being filtered off by the lungs and spleen; these bacilli, however, retained their vitality for some days. Sobernheim (1904) likewise found that the bacilli could live for weeks in the local infiltration produced in immunized sheep without undergoing any loss of virulence. From these experiments, it is clear that a number of bacilli may remain alive and virulent in the tissues without giving rise to disease.

The evidence that natural immunity to anthrax depends on the presence of β-lysins in the blood is unsatisfactory. There is no apparent relationship in different animal species between the presence of these substances and natural resistance to anthrax. It would appear rather that the most important protective mechanism is phagocytosis. Observations are at hand, however, that point to the presence of some other mechanism that prevents the proliferation of the organisms within the body. The nature of this mechanism is at present unknown.

Prevention, Vaccination, and Serum Treatment.

The usual hygienic measures should be adopted on the occurrence of anthrax in a herd. Every precaution should be taken to avoid contamination of the stall or pasture with blood or other fluid exuded from the animal. The carcass should be buried at a depth of 6 feet, or cremated. Other animals in the herd should be watched, and their temperatures should be taken before milking; any animal showing a rise of temperature should be isolated, and its milk withheld from distribution (M'Fadyean 1909).

Where the disease is epidemic, prophylaxis is best assured by vaccination. In countries in which the cases are sporadic, close attention should be paid to the artificial food-stuffs, as these appear to be responsible for a large proportion of the outbreaks.

The prevention of industrial anthrax in man is directed partly to disinfection of the imported animal products, wool, hides, horsehair, and so on, and partly to diminishing the risk of contact with dangerous material in the factories. For the various methods of disinfection, and for factory legislation, the reader is referred to textbooks of Hygiene. Briefly, however, the disinfection of bales and fleeces may be accomplished by preliminary treatment with warm alkali and soap, followed by exposure to a 2 per cent. solution of formaldehyde and drying in hot air (Legge 1934). Robertson (1932) recommends the use of H_2S for the disinfection of hides; anthrax spores are destroyed in 7–16 days.

Vaccination.—In 1879, Chauveau (1880*b*) found that an animal which survived inoculation with anthrax was more resistant to subsequent inoculations. The following year, Toussaint (1880*a*, *b*) successfully vaccinated sheep with defibrinated anthrax blood that had been heated for 10 minutes at 55° C. In 1881, Pasteur (1881*b*, *c*) introduced a method of vaccination, founded on the same principle as that which had been successful in diminishing the virulence of the organism of chicken cholera. He found that if the anthrax bacillus was cultivated in broth at 42–43° C., not only did it lose its power of forming spores, but it gradually decreased in virulence, till after 2 to 3 months it was no longer able to give rise to disease, even in the most susceptible animals. Pasteur prepared two vaccines; the first or *premier vaccin* was a subculture in broth from a strain that had been

kept at 42–43° C. for 15 to 20 days; its virulence was such that it could kill mice and young guinea-pigs, but was unable to kill adult guinea-pigs or rabbits. The second or *deuxième vaccin* was a subculture after 10 to 12 days; it was much more virulent, being able to kill mice, adult guinea-pigs and a certain proportion of injected rabbits.

Arrangements were made with the President of the Agricultural Society of Melun for a trial of this new method under field conditions. Accordingly on May 5, 1881, on a farm at Pouilly-le-Fort, 24 sheep, 1 goat and 6 cows received their first vaccination, and on May 17 they were vaccinated a second time with the more virulent but still attenuated strain. On May 31, Pasteur and his co-workers, Roux and Chamberland, inoculated each of the vaccinated animals with a virulent culture of anthrax; at the same time a series of control animals consisting of 24 sheep, 1 goat and 4 cows were similarly inoculated. Two days later, the vaccinated sheep and the goat were in perfect condition; the control sheep and the goat were all dead. The 4 unvaccinated cows were suffering from severe œdema and fever; the 6 vaccinated cows had neither fever nor œdema. The following day one of the vaccinated sheep died, but at necropsy it was found to be carrying a fœtus that had been dead for about a fortnight.

The success of this experiment led to the vaccination on a large scale of cattle and sheep in Europe, in South America, and in other countries. In 1894 Chamberland collected the statistics that were available for the years 1882 to 1893 inclusive (Table 168).

TABLE 168

RESULTS OF VACCINATION BY PASTEUR'S METHOD.

No. of sheep vaccinated	1,788,677
Mortality after 1st vaccine	5,668, or 0·32 per cent.
Mortality after 2nd vaccine	4,406, or 0·24 „
Mortality during the rest of the year	6,798, or 0·38 „
Total mortality	16,872, or 0·94 „
No. of oxen and cows vaccinated	200,962
Mortality after 1st vaccine	177, or 0·09 „
Mortality after 2nd vaccine	82, or 0·04 „
Mortality during rest of year	432, or 0·21 „
Total mortality	691, or 0·34 „

Before vaccination, the mean mortality of sheep was 10 per cent., of cattle 5 per cent. Chamberland calculated that vaccination had effected a saving of 5 million francs on sheep, and of 2 million francs on cattle.

In Germany, from 1901 to 1908, the total mortality of vaccinated cattle was 0·03 per cent., of horses 0·05 per cent., and of sheep 0·06 per cent. (Klimmer 1911).

At first sight these figures seem impressive, but further consideration suggests suspension of judgment. The method of comparing the mortality in vaccinated animals, during a given period, with the mortality amongst unvaccinated animals in a preceding period, is fallacious; there is no evidence to show that the conditions of the two sets of animals were identical. Large numbers of the vaccinated animals were never subsequently exposed to any risk of anthrax at all; hence no conclusions relative to their immunity can be drawn. Moreover, it would appear that anthrax in France is nearly as prevalent as it was before the vaccination era (Page 1909).

There have been many unfavourable reports on the Pasteurian method of vaccination. One of the chief objections is that it is difficult to standardize the virulence of the two vaccines exactly. Sometimes the virulence is too high, so that large numbers of animals die of the injection alone; sometimes it is too low and confers no protection. Pasteur stated that the decrease in virulence at 42–43° C. occurred gradually, so that at any moment it was possible to fix the virulence at a given point. It is fairly clear now that this statement was incorrect. Preisz (1911), in an illuminating article, showed that in a culture maintained at 42–43° C. bacillary variants appear, some of which possess no capsules and are avirulent, while others possess capsules and are highly virulent; intermediate forms, some spore-bearing, others non-spore-bearing, may appear, and may also differ in virulence. One and the same culture, therefore, may contain both highly virulent and quite avirulent varieties, besides a number of intermediate forms. Moreover, there is no strict relation between the length of incubation and the appearance of the different variants (see Chapter 35). These observations serve to explain the anomalous results of different workers, and show the difficulty of obtaining vaccines of fixed virulence by Pasteur's method.

Nevertheless there are now a few strains, like the Carbozoo and the Boshoff strains, that appear to have become stabilized at a fixed level of attenuation. One of these—the Carbozoo strain—has been used by Mazzucchi (1935) for the preparation of a vaccine in which the spores are suspended in a 2 per cent. solution of saponin; the object of the saponin is to bring about at the site of injection the early formation of gelatinous œdema which acts as a barrier against the rapid dissemination of the bacilli. Field tests with this vaccine have yielded very promising results, and it is now being used extensively in different parts of the world. More recently Sterne (1939) in South Africa has introduced a vaccine prepared by suspending avirulent uncapsulated sporing bacilli in 50 per cent. glycerol saline. Tests on 2½ million cattle and several thousand horses and sheep are reported to have shown that this vaccine gives as good protection as the saponin vaccine, and has the advantage of being safer and producing less reaction.

Reference may be made briefly to Cienkowsky's method, which consists of the use of two vaccines of spore-bearing bacilli attenuated by heat and standardized in virulence by repeated passage through gophers (*Zieselmaus*). It has been used chiefly in Russia, and also in Japan (Poppe 1922).

Sobernheim's Combined Method.—This is a method of combined active and passive immunization. Sobernheim (1902, 1904, 1906) prepared an immune serum by injection of cattle or sheep with cultures of increasing virulence. For his vaccine, he used a culture slightly attenuated by growth at 42·5° C. In practice, simultaneous injections are made, beneath the skin, of 10–16 ml. of immune serum and 0·5–1·0 ml. of vaccine. This method has been extensively adopted in Germany and South America, where it appears to have given good results. It has the merit of requiring only one injection instead of two; of conferring a passive immunity which protects the animal while an active immunity is developing; and of being attended by very little danger. It can be employed after an epidemic has broken out, without fear of rendering the animals more susceptible to infection.

None of the methods in use confers an immunity for more than 9 months or a year; hence vaccination must be repeated annually. It is extremely difficult to gather from the imperfect figures that have been reported what the value of vaccination really is. Instead of vaccinating alternate animals, and comparing

the mortality of the vaccinated with the control animals in the same herd, the experiments have nearly all been made by vaccination of the entire herd, and comparing the mortality of the vaccinated animals with that of the non-vaccinated animals during previous years. The evidence is therefore circumstantial, and cannot be considered satisfactory.

On the whole, however, vaccination does seem to be of value in districts in which the disease is rife. It should never be employed in countries where merely sporadic cases occur, for the living bacilli that are injected may actually help to spread rather than to restrict the disease. Of the various methods referred to, the saponin Carbozoo vaccine seems to enjoy the greatest favour at present for the routine immunization of large animals.

Serum Treatment and Chemotherapy.—Several workers have prepared an immune serum by injection of animals with cultures of increasing virulence, and have found it capable of conferring passive immunity on rabbits. Sobernheim, in particular, has obtained satisfactory results both for protective and for therapeutic purposes with immune sheep and cattle serum, but speaking generally the serum treatment of animals has never been employed on a large scale.

In man, on the other hand, serum treatment is of great importance, and Sclavo's serum appears to have given excellent results. Sclavo (1895) first immunized sheep, but later (1896, 1898, 1901) he found that the ass gave the most satisfactory results. In 1903 Sclavo collected 164 cases of anthrax treated with serum in Italy; there were 10 deaths or a mortality of 6·09 per cent. compared with a mortality of 24·1 per cent. for the whole of Italy (see Page 1909). Legge (1905) states that the mortality of cases treated early varies in different series from 7·1 per cent. to 15·4 per cent., as against 25 per cent. for untreated cases. In this country Eurich (1933) has had a mortality of only 5 per cent. in his last 200 cases of cutaneous anthrax. His treatment consists in never excising the pustule, except when it is in a site, such as the neck, where rapid extension is common, in immobilizing the part, in giving 80 ml. of Sclavo's serum intravenously or subcutaneously on the 1st day and 60 ml. on the 2nd, and in combining serum treatment with a moderately large dose of salvarsan on the 1st and 2nd days. This treatment is similar to that advocated in the United States (Report 1934–35).

Hodgson (1941, 1944) has reported a series of 107 cases of cutaneous anthrax treated without surgical excision of the lesion. Of 52 that were given serum only, 6 died; of 55 that were given serum plus neoarsphenamine (neokharsivan), none died. Serum is given in doses of 100 to 300 ml. each day for five days, with 0·3 gm. of neoarsphenamine on alternate days. Improvement is seldom evident in less than 36–48 hours. (See also Lucchesi and Gildersleeve 1941.)

Cruickshank (1939) found that in the treatment of experimental anthrax in the mouse sulphapyridine was far more effective than arsenical compounds. This conclusion seems to be borne out by Gold (1942), who treated 42 cases of anthrax with sulphonamides. Favourable results were obtained in 39 cases; the other three recovered under subsequent serum treatment. Though sulphapyridine appeared to be most active, Gold regards sulphathiazole as the compound o choice for general purposes. If there is no response within three days, serum should be substituted. It may be added that Murphy, La Boccetta and Lockwood (1944) have reported rapid recovery in three cases of cutaneous anthrax treated with penicillin.

The way in which the serum acts is unknown. It contains neither bactericidins

nor antitoxins; the agglutinin content is said to be no higher than that of normal serum; but Cler (1906) states that it contains opsonins and complement-fixing bodies. Sobernheim (1904) found that immune serum could be heated to 60–70° C., could be kept for 2½ years without any precautions, or could be frozen and thawed, without suffering any diminution of its protective power. Tomesik and Iványovics (1938) and Iványovics (1938*a*, *b*) find that it is possible to prepare two types of sera. One type, which can be obtained by injecting killed encapsulated bacilli into rabbits, contains capsular antibody. The other, which can be obtained by injecting rabbits, horses and certain other animals with living bacilli or with œdema fluid, contains antibody to the somatic polysaccharide substance but little or no capsular antibody. The first type of serum confers passive protection on mice, the second does not. On the other hand, animals producing the first type of serum are not themselves immune, whereas animals producing the second type are highly resistant. All the commercial sera so far examined appear to be of the second type. Which type of serum is of more value in human therapeutics is still doubtful. Until this question is settled, no satisfactory method of standardizing anti-anthrax serum can be proposed.

CHAPTER 77

TETANUS

History

This disease was described by Hippocrates, Aretæus, and others, but its nature remained obscure till Carle and Rattone in 1884 demonstrated its transmissibility to animals They injected a number of rabbits with a suspension of an acne pustule, which had been the starting-point of a fatal attack of tetanus. The injections, which were made into the sciatic nerve or into the back muscles, were followed in 2 or 3 days by tetanus. The disease could be transmitted to fresh animals by injection of a suspension of nerve tissue.

In the same year Nicolaier (1884, 1886), working at Göttingen, found that the inoculation of earth into mice, guinea-pigs, or rabbits was frequently followed by a disease closely simulating human tetanus. In the pus at the site of inoculation, besides cocci and other organisms, he noticed long, thin bacilli, resembling, but rather larger than, Koch's bacillus of mouse septicæmia (*Ery. muriseptica*). Though he was unable to isolate this organism in pure culture, he grew it in deep coagulated serum for seven generations, and reproduced the disease by injection of the last culture. In animals dying of the experimental disease Nicolaier was unable to find these bacilli microscopically except in the local lesion and, occasionally, in the sciatic nerve sheath and spinal cord. Their limited distribution led him to suggest that the organisms multiplied locally and produced a strychnine-like poison, which, on absorption, reproduced the disease. In 1886 Rosenbach observed a similar bacillus with a round terminal spore in a human case of tetanus, and the pus proved infective to animals. The final demonstration of the ætiological rôle of the tetanus bacillus was furnished in 1889 by Kitasato, who isolated it in pure culture from pus. This he accomplished by heating the pus to 80° C. for 45 to 60 minutes to destroy non-sporing organisms, plating out on gelatin, and incubating in an atmosphere of hydrogen. The inoculation of pure cultures into animals was successful in reproducing the disease.

Epidemiology.

A. Incidence.—Tetanus is an infective disease resulting generally from the contamination of a wound or raw surface, and characterized by a series of tonic muscular spasms usually commencing in the neighbourhood of the site of infection. The frequency with which the masseter muscles are involved has given rise to the popular term lockjaw. In mild cases the spasms may remain localized, but as a rule they become general and involve the whole of the somatic muscular system. In infants the cut surface of the umbilical cord may afford an entrance to the bacilli—tetanus neonatorum; and in mothers tetanus occurs, though very rarely,

as the result of infection in the post-partum genital tract. Infections of the face or head give rise to a peculiar form—cephalic tetanus—characterized by facial paralysis and dysphagia. Visceral tetanus is an uncommon form, in which infection appears to originate from the bacilli in the intestinal tract.

In this country the disease is comparatively uncommon. From 1915 to 1924 the mean annual number of civilian deaths in England and Wales was 157·7, of which 123·2 were in men and 34·5 were in women. But in other countries, particularly the tropics, the disease is more widespread. In 1909 there were 1,373 deaths from tetanus amongst 732,528 deaths from all causes in 18 states of North America; of these 30·7 per cent. were in children under 1 year (Osler 1920). At one time the 4th July celebrations were followed by a large number of cases, usually resulting from blank cartridge wounds (Smith 1908).

Tetanus has followed the administration of gelatin for the control of hæmorrhage, of vaccine lymph, of antitoxic sera, of bacterial vaccines, and the insertion of catgut (Smith 1908).

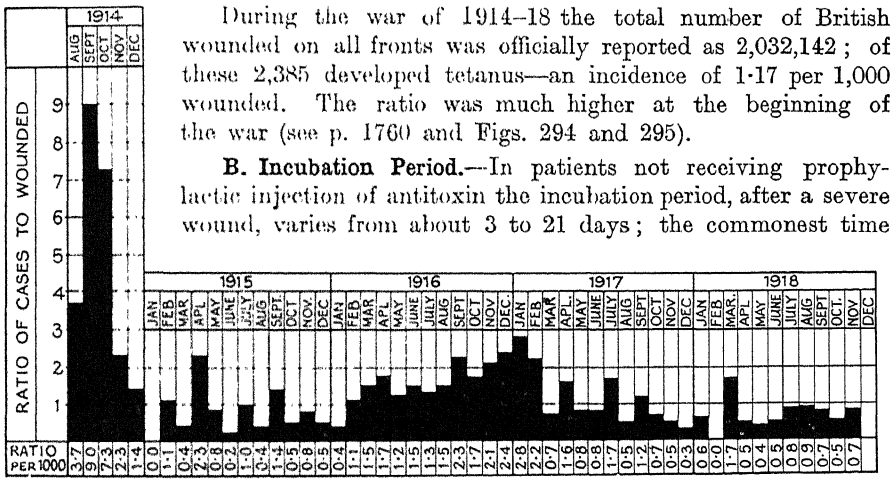

FIG. 294.

The ratio per 1,000 of cases of tetanus to wounded. (After Bruce.)

During the war of 1914–18 the total number of British wounded on all fronts was officially reported as 2,032,142; of these 2,385 developed tetanus—an incidence of 1·17 per 1,000 wounded. The ratio was much higher at the beginning of the war (see p. 1760 and Figs. 294 and 295).

B. Incubation Period.—In patients not receiving prophylactic injection of antitoxin the incubation period, after a severe wound, varies from about 3 to 21 days; the commonest time of onset is about the 7th day. During the war the incubation period increased enormously—partly on account of the use of antitoxin prophylactically; thus in cases treated in home hospitals, the incubation period increased from an average of 11·8 days in 1914 to 50 days in 1918–19 (Bruce 1920).

C. Mortality.—This depends on the nature of the wound, the site of infection, and the treatment accorded. Severe wounds, especially if deep, lacerated, or badly soiled, are characterized by a high mortality. Wounds of the upper extremities are more dangerous than those of the trunk or lower extremities (Bruce 1920). Tetanus neonatorum is very fatal.

The earlier the onset of symptoms, the more likely is death to occur (Table 169) (Bruce 1920).

In pre-serum days the case mortality was about 85 per cent. (Bruce 1920). Bruce (1915, 1916, 1917*b*, *c*, *d*, 1919, 1920) reports on 1,458 cases of tetanus

TABLE 169

SHOWING THE RELATION BETWEEN THE LENGTH OF THE INCUBATION PERIOD AND THE MORTALITY IN TETANUS.

Length of Incubation Period.	No. of Cases.	Case Mortality per cent.
2–10 days	294	58·1
11–22 days	477	35·3
Over 22 days	579	17·3

that were treated in home hospitals during the war of 1914–18. After 1914 almost every patient had received one or more prophylactic inoculations of antitoxin; the majority had also been treated therapeutically with antiserum. The mortality from tetanus of these cases was as follows (Table 170):

TABLE 170

MORTALITY OF CASES OF TETANUS IN THE WAR OF 1914–18.[1]

Year.	No. of Cases.	Died of Tetanus.	Recovered.	Percentage Mortality.
1914 . . .	182	101	81	55·5
1915 . . .	138	78	60	56·5
1916 . . .	451	170	281	37·7
1917 . . .	376	76	294	20·5
1918 . . .	291	73	204	26·4
1919 . . .	20	3	16	15·8

[1] 21 cases dying from causes other than tetanus have been excluded.

Amongst cases of tetanus developing in France or Belgium and treated abroad the mortality was very much higher. In the spring of 1915 amongst 179 cases there were 140 deaths—78·2 per cent. case mortality. Between July and October, 1916, Leishman and Smallman (1917) reported on 160 cases with a mortality of 73·7 per cent. And between November, 1916, and December, 1917, Cummins and Gibson (1919) reported on 376 cases with a mortality of 67·0 per cent. The higher mortality in France was no doubt due to the fact that cases of tetanus with a short incubation period were treated abroad, whereas those in which this period was longer were generally evacuated to England.

D. Distribution of Tetanus Bacilli.

SOIL.—Nicolaier (1884) demonstrated the presence of tetanus bacilli in 12 out of 18 samples of earth. Some of the specimens—from Leipzig and Berlin—had been kept for years. In this country Fildes (1925*a*) examined 70 specimens of soil from waste and cultivated lands, and found *Cl. tetani* 33 times. In Baltimore, Gilles (1937*a*) found toxigenic strains in 9 of 63 samples of street dust.

ANIMAL FÆCES.—Toledo (Toledo and Veillon 1891) demonstrated the presence of *Cl. tetani* in horse and in cow dung. Noble (1915) found it in 18 per cent. of 61 samples of horse fæces examined, but not in any of 21 samples of cow fæces. Sanfelice (1893) demonstrated it in 7 out of 23 samples of normal guinea-pig fæces. Fildes (1925*a*) isolated it from 34 out of 200 samples of normal horse

fæces from London stables. Kerrin (1929) found it in 8 out of 53 samples of horse fæces, 4 out of 21 samples of cow, 6 out of 23 samples of sheep, 17 out of 37 samples of dog, 52 out of 141 samples of rat, and 6 out of 34 samples of hen fæces. Approximately half of the strains proved to be atoxic.

HUMAN FÆCES.—Pizzini (1898) demonstrated the presence of *Cl. tetani* in human fæces; he found it in 3 out of 10 samples from ostlers, and in 2 out of 90 samples from peasants. On the basis of these results, it has been generally assumed that contact with horses strongly predisposes to the carrier condition in man, but we doubt if this assumption is justified. In this country Tulloch (1919–20) found the tetanus bacillus in 5 out of 31 specimens of fæces, and Fildes (1925*a*) only twice in 200 specimens, while Kerrin (1928, 1929) failed to find it once in an examination of 304 samples of adult stools. Similarly Scheunemann (1931) in Germany was unable to isolate it from 50 samples of human fæces. The tetanus bacillus must be ingested frequently with raw food, but the evidence suggests that it is an organism of passage, which does not find a natural habitat in the human intestine.

Reproduction of the Disease in Animals.

Tetanus can be reproduced by the inoculation of pure cultures or of toxin into mice, rats, guinea-pigs, rabbits, goats, sheep, horses, and monkeys. Cats and dogs are more resistant; birds and cold-blooded animals are highly resistant. The most susceptible animal, calculated on the amount of toxin per gram of body weight necessary to prove fatal on injection, is the horse. This is about 12 times as susceptible as the mouse; the guinea-pig is 6 times, and the monkey 4 times, as susceptible as the mouse (von Lingelsheim 1912, Sherrington 1917). On the other hand, the rabbit is twice, the dog 50 times, the cat 600, and the hen 30,000 times as resistant as the mouse (Kitasato 1891, von Lingelsheim 1912). For a description of the lesions produced in laboratory animals reference should be made to Chapter 36.

Mode of Infection in Tetanus.

Vaillard and Rouget in 1892 found that, if tetanus cultures were heated to 65–67° C. for half an hour to destroy the vegetative bacilli and the toxin, the toxin-free spores remaining could be injected in large numbers into a guinea-pig without giving rise to the disease. Microscopical examination showed that the spores did not germinate in the tissues, but were rapidly taken up by the phagocytes, so that in 2 or 3 days they were completely ingested. If, however, the spores were protected from the phagocytes by being wrapped in filter paper, they germinated and gave rise to fatal tetanus. The same results could be obtained by inflicting a trauma at the site of injection, sufficient to cause tissue necrosis or effusion of blood, or by creating a simple fracture. In the damaged tissue the spores were able to germinate, whereas in clean, aseptic wounds they were unable to do so. The presence of other organisms, particularly aerobic, in the wound also permitted the germination of the spores. From these observations it appears that toxin-free spores are innocuous, but that they can be activated by injuring the tissues or by a secondary infection.

These observations were extended by several workers, of whom, for the sake of convenience, we may quote one of the latest. Francis (1924) found that toxin-free spores were rendered pathogenic for guinea-pigs by the simultaneous injection of staphylococci, or of a tissue debilitant such as quinine. He also observed that if either of these agents

was inoculated some time after the injection of the spores, tetanus frequently developed. The result depended on the time elapsing between the two injections. When the spores and the accessory agent were given simultaneously into the same site, all the animals died; when the accessory agent was given into the same site 9 to 30 days after the spores, 11 out of 24 of the animals died; and when the interval was between 30 and 90 days, only 2 out of 20 died. These experiments show clearly that the spores may survive in the tissues for some time. This confirms the work of Vaillard and Rouget (1892), who found that though the spores were rapidly ingested by phagocytes, they were not necessarily destroyed, but might remain latent within the cells, and spontaneously give rise to tetanus some months afterwards (idiopathic tetanus). Francis concluded that in guinea-pigs they nearly all perished within 30 days, but that in mice they remained latent for at least 4 months.

During the war of 1914–18, renewed interest was taken in the mode of infection. Numerous observations showed the presence of the tetanus bacillus in the wounds of men who manifested no symptoms of the disease. Thus in an examination of 100 soldiers not suffering from tetanus, Tulloch (1919–20) found the bacillus 19 times. Observation also showed that tetanus might not develop for weeks or months after the wound had healed, and might then appear suddenly after an operation, perhaps on another part of the body. There is on record a number of cases in which tetanus developed up to 14 years after the presumed introduction of the spores into the tissues; and Bonney, Box and MacLennan (1938) described one case in which tetanus bacilli were isolated from the uterine tissue ten years after an operation which had at the time been followed by a typical attack of tetanus.

Repeating the experiments of previous workers, Tulloch (1919–20) found that toxin-free tetanus spores injected into animals could be stimulated to activity by the simultaneous inoculation of tissue debilitants, such as lactic acid, saponin, and trimethylamine. The results were not always satisfactory; moreover the type of debilitant necessary to prove effective varied with the species of the animal. He then tried the action of *Cl. welchii* and *Cl. septicum* toxins, and found that the addition of a sublethal dose of toxin to tetanus spores enabled the latter to germinate and give rise to a fatal disease.

Bullock (Gye) and Cramer (1919) made an important contribution to the subject when they discovered that the injection of small quantities of ionizable calcium salts together with toxin-free spores invariably led to the development of tetanus. About 2–3 mgm. of $CaCl_2$ was sufficient for a mouse, and about double this quantity for a guinea-pig. Using washed bacilli—but not spores—the same result was obtained whether the bacilli and the salt were injected into different sites at the same time, or into the same site at different times. Further examination led them to conclude that the effect of the calcium ions was not to alter the virulence of the bacteria or the potency of the toxin, but to produce a local change in the tissues at the site of injection. When the calcium salt and the bacilli were injected at different sites, the lesion occurred at the site of injection of the salt; here, it is stated, the organisms were present in large numbers and were not ingested by phagocytes, whereas at the site of injection of the bacilli they underwent lysis and rapid phagocytosis.

It was further observed that soil had much the same action as that of the pure calcium salt. When, however, the calcium salts in the soil were precipitated by sodium carbonate, the watery extract no longer proved effective. They therefore came to the conclusion that one of the factors in allowing the germination of tetanus spores in a wound is the

presence of ionizable calcium salts. Under natural conditions these are frequently introduced with the earth contaminating the wound. The fact that calcium salts are more abundant in cultivated than in waste soil, and that tetanus was far commoner at the beginning of the war, when the fighting was mainly on the highly cultivated soil of Flanders than towards the end, when the soil had largely become waste, led them to suggest that there might be a causal relationship between the diminution of the calcium salts in the soil and the decrease in the incidence of tetanus.

Careful investigations by Fildes (1927) and Russell (1927) suggested very strongly that the germination of tetanus spores in the tissues is dependent chiefly upon the oxidation-reduction potential of the tissues. Histological examination of the tissues of guinea-pigs inoculated with spores revealed the fact that phagocytosis was always incomplete, and could not therefore be held responsible for the failure of the spores to germinate. It was observed that germination never occurred when the heated spores alone were injected; and that when a mixture of spores and earth was injected, germination occurred only in the small areas of necrosis produced by the earth. Calcium chloride was found to produce a widespread necrosis; spores inoculated at the same time germinated over the whole of the necrotic area. Fildes considered that in the normal tissues the O–R potential is sufficiently high to prevent the spores from germinating; but that in areas of necrosis the potential falls to a point sufficiently low to permit of their germination. He would ascribe in fact the same importance to the O–R potential in determining the germination of spores *in vivo* as *in vitro*.

Further observations by Fildes (1929*a*, *b*) and his colleagues (Knight and Fildes 1930, Campbell and Fildes 1931), have greatly strengthened this view. It was found that tetanus spores were unable to germinate in a medium of pH 7·0–7·6 unless the oxidation reduction potential was reduced to Eh + 0·01 volt or below. The Eh of the subcutaneous tissue of the guinea-pig was found to be above this level. If, however, the partial pressure of oxygen in the tissues was lowered by keeping the animals in an atmosphere containing only 7 per cent., instead of the normal 21 per cent., of oxygen, then the Eh was reduced to a level at which germination of the spores in the presence of a mild activating agent such as aleuronat was often rendered possible. (See also p. 1206.)

The observations of Wámoscher and von Vásárhelyi (1933) also support Fildes' explanation. These workers found that one of the most successful activating agents was a small piece of sterile agar. This acts presumably, not by causing an area of focal necrosis in the tissues, but by furnishing a nidus, cut off from the blood supply, in which the Eh is sufficiently low to enable tetanus spores to germinate.

From these observations we may form a conception of the genesis of tetanus in the body. When tetanus spores are introduced into a wound by contamination with earth, horse fæces, or other material, their fate depends largely on the presence or absence of certain accessory factors. Many of these have been described—notably trauma, hæmorrhage, tissue necrosis; chemicals such as lactic acid, saponin, trimethylamine, colloidal silicic acid, and ionizable calcium salts; and biological substances such as the toxins of *Cl. septicum* and *Cl. welchii*. Which of these factors is the more important it is impossible to say; recent work tends to ascribe less importance to mechanical injury, and more to calcium salts and the toxins of other anaerobes. The presence of a suitable accessory factor enables the spores to germinate and multiply in the tissues; it seems probable that this action is dependent on the production by tissue debilitants of an area of necrosis with a sufficiently low oxidation-reduction potential to permit the spores to germinate. In post-operative tetanus the spores may be derived either from infected catgut (see Mackie 1928, Mackie *et al.* 1929, Bulloch 1929), imperfectly sterilized instruments or dressings, or some other source such as the intestinal or the respiratory tract (see Carbone and Perrero 1895, Motzfeldt 1912, Wright 1930).

Absorption and Mode of Action of Tetanus Toxin.

The absorption and mode of action of tetanus toxin has provided a problem of extraordinary interest to experimental workers. The field covered has been so wide that it is impossible to do more than give here an outline of some of the more important experiments. Those who are interested in the subject will do well to consult the papers of Abel and his colleagues (see p. 1753), which give a far more adequate historical survey than we can provide.

If a guinea-pig is injected with a culture of tetanus bacilli, and allowed to develop the disease and die, it is found that scrapings from the site of inoculation are very rich in toxin; in fact, Francis (1924) calculated that the scrapings from a single animal would be sufficient to kill 4,800 mice. On the other hand the blood serum of the dead guinea-pig contains only a minimum amount of toxin, perhaps just sufficient in 1 ml. to kill one mouse; while the organs are completely non-toxic (Rosenbach 1886, Kitasato 1891). Even the central nervous system, in which the toxin might be suspected of accumulating, is harmless on injection into animals (Kitasato 1889, Meyer and Ransom 1903).

The toxin does not appear to be absorbed by the blood to any great extent, because in the first place the toxin content of the blood is very low, and secondly, in order to produce fatal tetanus, more toxin is required when given by the blood stream than when injected subcutaneously; moreover, with a given dose of toxin the incubation period is longer after intravenous than after subcutaneous inoculation.

Bruschettini (1890, 1892) induced tetanus in rabbits by the injection of toxin beneath the skin or into the sciatic nerve; suspensions of the organs were made and injected into fresh animals. The blood and kidneys proved toxic; the lumbar enlargement of the cord was sometimes toxic after subcutaneous, and invariably after intraneural, injection. He concluded that part of the toxin found its way into the blood stream, whence it was excreted by the kidneys; and that part was absorbed by the peripheral nerves and carried to the central nervous system.

In 1897 Marie found that the direct injection into the sciatic nerve of a sub-lethal dose of toxin was sufficient to provoke a fatal attack of tetanus in a rabbit. But if a lethal dose was injected into the forepaw of a rabbit, whose 2nd cervical nerve on that side had been cut, tetanus failed to develop. These observations suggested that the toxin was absorbed by the peripheral nerves and conveyed to the spinal cord; if these nerves were cut, the toxin was unable to reach the cord, and hence tetanus did not occur.

This suggestion was confirmed by Meyer, who found that the sciatic nerve of an animal into whose foot an inoculation had been made was toxic to other animals. Marie and Morax (1902) repeated this with similar results, and added further important information. Thus, they showed that the peripheral nerves can take up toxin only if their nerve endings are intact. The absorption occurs rapidly; for example the sciatic nerve of a guinea-pig which has been injected in the foot is toxic to mice in a little more than an hour after the inoculation. Further experiments suggested that the toxin passed up the axis cylinders in a centripetal current towards the spinal cord. Thus if the sciatic nerve is cut at the popliteal space some time after inoculation of toxin into the calf, the central end rapidly loses its toxicity. If the toxin is injected directly into the lumbar cord, the sciatic nerves remain free from toxin, whereas both the lumbar and the dorsal cords contain considerable amounts.

Meyer and Ransom (1903), using somewhat different methods, came to very much the same conclusions as Marie and Morax. They injected antitoxin into the right sciatic nerve of a rabbit, and then injected toxin subcutaneously into both hind legs. Tetanus developed in 2 or 3 days, but commenced in the left leg; the right leg remained unaffected. In other words, the antitoxin had apparently blocked the passage of the toxin up the sciatic nerve of the right side, and prevented its reaching the cord.

Again, they injected toxin intravenously into a cat, and on the same day injected the

sciatic and femoral nerves with antitoxin; the cat developed general tetanus with the exception of the hind legs which appeared normal. Their experiments seemed to show that the toxin was absorbed by the motor nerves, up which it passed to the spinal cord, where it exerted its effect on the anterior horn cells. If this is so, then the direct injection of toxin into the anterior portion of the cord should be followed rapidly by tetanus. This deduction is correct. Meyer and Ransom, in fact, found that under these conditions the first symptoms of tetanus in a cat appeared in about 3 hours. This seems to explain why, after injection of pure toxin into a limb, there is an incubation period before the disease manifests itself. This period is occupied in the absorption of the toxin by the nerve endings and its passage upwards to the cord. As a rule, the smaller the animal and the less the distance the toxin has to travel along the nerves, the shorter is the incubation period. In the mouse, for example, it is about 12 hours, in the rabbit 18 to 36 hours, in the dog 36 to 48 hours, and in the horse 5 days (Meyer and Ransom 1903). The dose of toxin administered is also a determining factor. The larger this is, the shorter is the incubation period.

It is necessary for the toxin to reach the anterior horn cells of the cord; this it does by passing up the motor nerves. If the toxin is injected into the posterior roots between the ganglion and the cord, tetanus, as it is generally understood, does not occur. Moreover, if the toxin is injected into a part of the body devoid of motor nerves such as the testicles or the peritoneum, a peculiar form of splanchnic tetanus develops, characterized by a longer incubation period, a more rapid illness, and an absence of muscular spasms (von Lingelsheim 1912).

Summarizing, we may say that *the evidence hitherto quoted* suggests that the toxin, when injected into a limb, is absorbed chiefly by the motor nerve endings; thence it passes up the axis cylinders to the anterior horn cells. Not until these have been reached, do symptoms of tetanus appear. At first the contractions are confined to the injected limb; but later, as the toxin diffuses through the cord, the opposite limb and finally the muscles over the whole body become affected. A small amount is probably absorbed by the lymph and carried to the blood stream. From this it is taken up by the motor nerve endings in different parts of the body. Hence the tetanus developing after intravenous injection of toxin is slower in its development, but is generalized from the first.

This conception of the genesis of tetanus has received very severe criticism from Abel (1934) and his colleagues (Abel and Hampil 1935, Abel *et al.* 1935*a*, *b*, Abel, Evans and Hampil 1936, Firor and Jonas 1938, Abel *et al.* 1938, Abel, Firor and Chalian 1938).

Briefly, these workers object to the hypothesis of axis cylinder carriage on the ground that (1) there is no evidence to show that the axis cylinders ever contain tetanus toxin; (2) there is no known mechanism that will explain how the toxin is transported in the axis cylinders, often for long distances, to the central nervous system; (3) the injection of a sub-lethal dose of toxin directly into the sciatic nerve of the dog does not give rise to tetanus, provided measures are taken to prevent the escape of the toxin into the surrounding tissues; and (4) the injection of antitoxin into the sciatic nerve, provided none leaks into the surrounding tissues, does not prevent the development of local tetanus after injection of toxin into the muscles of the leg.

A second hypothesis, which has been held by some workers, that the toxin is carried to the central nervous system by the endoneural and perineural lymphatic vessels, seems to be ruled out on anatomical grounds. There is no evidence to show that the neural lymphatics drain into the cerebrospinal fluid; on the contrary the evidence seems fairly conclusive that they drain directly into lymph glands, which in their turn drain into the thoracic duct.

Discounting these two hypotheses, as well as that of the transference of the toxin

in the tissue spaces of the nerve trunks by molecular forces, Abel adopts the view that the toxin reaches the central nervous system by the arterial circulation. Contrary to the findings of certain previous workers, he has been able to show that, if doses greater than the minimal lethal dose are used, a very high proportion of the toxin injected into the limb of a sheep may be demonstrated in the lymph-glandular and vascular systems. Minimal lethal doses of toxin are fixed by neural and other tissues, so that the toxicity of any tissue for experimental animals into which it is injected results entirely from the presence of blood or lymph containing free toxin. Secondly, Abel believes that tetanus toxin has a dual action on the central and on the peripheral nervous system. By means of multiple injections at various points of a limb, he has produced local tetanus in dogs with amounts of toxin so small that generalized tetanus never develops. Intravenous toxin, on the other hand, produced both the local muscular rigidity and the reflex excitability of the muscles that characterizes generalized tetanus; while the application of toxin directly to the cord in the region of the anterior horn after a latent period of one to two hours produced the reflex excitability alone. The abolition of local tetanus by section of the appropriate nerve depends, not on the destruction of the path by which the toxin reaches the anterior horn cells, but on the abnormally low tonicity of the motor end-organs.

The hypothesis of a dual action is supported by the work of Harvey (1939) and Schaefer (1944). Harvey found that the intramuscular injection of sub-lethal amounts of toxin in divided doses produced local tetanus not only when the nerve was intact but also when the nerve was cut, *provided that* degeneration had not occurred. Section of the nerve diminished the rigidity, but did not abolish it. From a consideration of the electrical activity in tetanic muscle and the response to curarine, Harvey concluded that the integrity of the nerve ending, not its connection with the C.N.S., was essential for the genesis of local tetanus. He suggested that the toxin might act by increasing the normal leak, and in consequence the synthesis, of acetyl-choline in the end-organs, and by interfering with choline-esterase production. From similar considerations, Schaefer supports the notion of local action by the toxin, and claims to have demonstrated a raised acetyl-choline content in tetanic muscle. He found no evidence of any interference with choline-esterase by the toxin.

The establishment of a dual action of the toxin, on end-organs and on the anterior horn cells or their synapses, would not necessarily support Abel's general hypothesis of an exclusively blood-borne intoxication in tetanus, though it would clearly remove one of the outstanding objections to it. Another objection, made by Friedemann, Zuger and Hollander (1939*a*), is based on experiments indicating a selective impermeability of the capillaries and the central nervous system to tetanus toxin, which they attribute to a peculiarity of the toxin molecule. The toxin must, of course, pass through capillary walls in other tissues, otherwise on any hypothesis intravenous injection of toxin would be without ill effect. There is evidence that the capillaries of the brain may differ from those of the rest of the body in their permeability to various circulating dyes (see Friedemann 1942), but its applicability to the problem of tetanus toxin is contested (see, for example, Doerr 1940). In this connection we may note that Barnes and Trueta (1941), who immobilized the limbs of rabbits in plaster, found that several lethal doses of toxin could be injected into such limbs without ill effect. When after some days the plaster was removed tetanus followed. If we assume an intact blood circulation, it appears that toxin was not absorbed into the blood capillaries; the restoration of movement in the leg might have promoted absorption by the lymphatics, or the diffusion of the toxin to large numbers of end-organs throughout the muscle.

The observations of Friedemann and his colleagues (Friedemann, Zuger and Hollander 1939*a*, Friedemann, Hollander and Tarlov 1941) on the genesis of tetanus in the guinea-pig go far to restoring the position attacked by Abel.

They found that the amount of circulating antitoxin which protected an animal from death was determined by the route of injection of the toxin. With intramuscular toxin, this amount was up to 80 times as great as that needed when the same dose of toxin was given intravenously; but if the motor nerves supplying the injected part were cut, the protective amount of antitoxin was the same for both routes of injection, suggesting that in the intact animal, a considerable amount of toxin reached the central nervous system by some route other than the circulation. They noted that fatal tetanus followed the local injection of toxin in animals whose circulation contained, up to the time of death, a large excess of antitoxin; and, by transection of the cord, were able to limit the tetanus, induced by injection of toxin into one hind limb, to structures innervated from the cord below the level of section. Moreover, in transected animals, tetanus occurred in both hind limbs, due apparently to a migration of toxin across the cord below the level of transection.

Summarizing, we may say that we are still ignorant of the exact mechanism by which tetanus toxin is absorbed, and of the way in which it exerts its action on the body cells. The two main hypotheses are (1) that the toxin is absorbed by the motor nerve endings, and carried up the axis cylinders to the anterior horn cells of the central nervous system, which are then stimulated to produce muscular contractions; (2) that the toxin acts locally on the motor nerve endings, and centrally on the anterior horn cells, which it reaches via the lymphatic vessels and the blood stream.

One difficulty in deciding between these hypotheses lies in the variety of experimental animals—cats, dogs, guinea-pigs—investigated. What is true for the rabbit and guinea-pig may not hold for the cat or the dog. Some of the data upon which the first hypothesis was based are capable of other interpretations, and the hypothesis of dual action merits serious consideration. There are nevertheless certain facts which, if confirmed, cannot be reconciled with the second hypothesis.

With regard to the main assumption in the first hypothesis, the transmission of toxin along the axis cylinder, little can profitably be said. There is no evidence of a protoplasmic flow in the axis cylinder by which toxin could be carried, and it seems likely that movement by diffusion, especially of a substance known to be readily fixed to neural tissue (see p. 1756), would be exceedingly slow. In support of a ready movement of toxin along the axis cylinders it is customary to cite the transmission of neurotropic viruses like poliomyelitis. The analogy must be used with caution, for toxin lacks at least one important property of viruses—namely the power to multiply within the nerve cell itself. Nevertheless, if the available evidence points to the occurrence of axis cylinder carriage, we must not allow our ignorance of the way in which such transmission is effected to prevent us from drawing the logical conclusions.

Immunity to Tetanus.

Natural.—Mammals vary in their susceptibility to tetanus; some, such as the mouse, the monkey, and the horse are highly susceptible; others, such as the dog and the cat, are much less susceptible. Most birds and cold-blooded animals are extremely resistant. Examination of the blood of susceptible and partially susceptible animals shows that, while the majority of cattle contain more than 1/500 unit of antitoxin per ml., no antitoxin is present in the blood of man, horses, dogs, pigs, monkeys, or rodents. Sheep and goats may contain small quantities (Coleman 1931, Coleman and Meyer 1926, Ramon and Lemétayer 1934, 1935). The frequent

presence of antitoxin in the blood of ruminants may be causally associated with the comparative resistance of these animals to tetanus. It is suggested that in ruminants tetanus bacilli multiply and form toxin in the digestive reservoirs which precede the true stomach, and that the toxin so formed, partly modified perhaps by the products of bacterial fermentation, is absorbed and gives rise to the production of antitoxin. Examination of the blood of naturally resistant animals has proved it to be devoid of antitoxin (Vaillard 1892); hence their immunity cannot be attributed to the presence of this antibody.

Marie (1897) injected a rabbit intravenously with 1,000,000 mouse M.L.D. of toxin. Blood was removed at frequent intervals, defibrinated, and injected in 1 ml. quantities into mice. For the first 17 hours the blood proved toxic, but after this time it became innocuous; the toxin had disappeared therefore from the circulation in less than a day. Vaillard (1892), on the other hand, who injected a hen with 20 ml. of toxin, found that it persisted in the blood stream for several days. In the susceptible rabbit the toxin is supposed to be absorbed from the blood by the motor nerve endings, and carried to the cord, where it gives rise to disease. In the non-susceptible hen the toxin does not appear to be absorbed at all, or only slowly; hence tetanus fails to develop.

An interesting contribution to the study of natural immunity was made by Wassermann and Takaki (Wassermann 1898, Wassermann and Takaki 1898), who found that the brain, and to a less extent the spinal cord, of normal animals was able to neutralize tetanus toxin. A mixture of toxin and brain suspension proved harmless on injection into animals. The amount that could be neutralized depended partly on the animal; a guinea-pig's brain, for example, could neutralize completely 10 M.L.D. of toxin, and incompletely 60 M.L.D. They found moreover that the neutralization could occur in the body; a mouse injected with a brain suspension, and 24 hours later given 3 to 5 M.L.D. of toxin, did not develop tetanus. From these experiments they concluded that the brain contained natural antitoxin.

As was to be expected, a number of workers immediately directed their attention to this interesting phenomenon (Marie 1898, Metchnikoff 1898*a*, *b*, Roux and Borrel 1898, Danysz 1899, Marie and Morax 1902). They all confirmed the original observation of the *in vitro* neutralization of toxin by a suspension of brain tissue, but differed from Wassermann and Takaki in their explanation of it. It was found that the cells of the cerebral cortex were most active; that the brain of mammals was more powerful than that of birds and cold-blooded animals; that the neutralizing agent was insoluble in saline; that the union between the toxin and nerve cells was not permanent; that there was no actual destruction of toxin; and that for neutralization to occur there must be an intimate contact between the toxin and the cells. Protection experiments failed completely unless the two substances were inoculated at the same site. It is clear, therefore, that the brain does not act by virtue of its antitoxin content. The nervous tissue of the susceptible mammal has a strong affinity for tetanus toxin and, by combining with it, prevents its transference to the motor cells of the inoculated animal. On the other hand, the nervous tissue of the resistant hen, frog, and turtle (Metchnikoff 1898*a*) has little or no affinity for the toxin, and hence fails to anchor it. That this is the true explanation seems apparent from Roux and Borrel's work (1898), which showed that the lethal dose of toxin given directly into the brain of a rabbit was smaller than that necessary when given subcutaneously. The brain tissue of a susceptible animal resembles antitoxin in combining specifically with toxin, but with fatal effects to the animal concerned.

These observations also explain the fact that the central nervous system of animals dying of tetanus may appear to be devoid of toxin, when in reality it contains a considerable amount. To demonstrate the presence of the toxin it is only necessary to grind the brain up in 10 per cent. saline and to leave the suspension for some time, when the toxin will break away from the disintegrated cells and appear free in the fluid (Tizzoni and Cattani 1891*a*).

Acquired Immunity.—One of the most important advances in the progress of bacteriology was made by Behring and Kitasato (Behring and Kitasato 1890, Kitasato 1891, 1892, Behring 1892), when they discovered that the injection of a filtered culture of tetanus bacilli into an animal stimulated the production of an antibody which was able to neutralize the toxin and to preserve the life of animals injected with it. It protected not only against injections of toxin, but also against inoculation of the tetanus bacillus itself. Thus, if 0·2 ml. of an antitoxic rabbit's serum was injected intraperitoneally into a mouse, and virulent tetanus bacilli were injected subcutaneously 24 hours later, the mouse remained perfectly well. The nature of the union between toxin and antitoxin has been discussed elsewhere (see Chapter 46). We may here confine ourselves to a consideration of its protective action in practical prophylaxis.

The antiserum acts, not by interfering with the germination of spores, nor with the multiplication of the bacilli in the tissues, but by neutralizing the toxin as fast as it is formed. If antitoxin is present in the circulating blood and lymph, it will neutralize the toxin before the latter has time to gain access to the nerves. If the antitoxin is not given till after the formation of toxin has begun, it will be too late to prevent the absorption by the nerves.

It follows that there are rigid conditions governing the usefulness of antitoxin. The most important of these is that it must be allowed to come into intimate contact with the toxin. Unless it does so it is valueless. It is known that the nervous tissue of mammals has a strong affinity for tetanus toxin ; it has no such affinity for tetanus antitoxin. Once the toxin has gained entrance to the nerves it can no longer be neutralized, unless the antitoxin is itself injected into the nerves. Meyer and Ransom (1903) injected antitoxin in large quantities intravenously into a cat, and at the same time injected a dose of toxin into the sciatic nerve ; the cat developed tetanus. The nerve tissue acts as a barrier separating the toxin from the antitoxin ; and nothing short of enormous doses of antitoxin in the blood stream can save the life of an animal if once the toxin has gained access to the nerves. We have, in fact, the anomaly of an animal, whose blood contains sufficient antitoxin to save the life of hundreds of mice, itself dying of tetanus. If the antitoxin is injected directly into the central nervous system, there is some evidence that it is able to neutralize the toxin and prevent further spread of the disease (Roux and Borrel 1898). Roux and Borrel's interpretation of their findings is open to question (see Abel and Hampil 1935), though in more carefully controlled experiments Friedemann, Hollander and Tarlov (1941) demonstrated the superiority of intraventricular over intravenous antitoxin in preventing local tetanus. Roux and Borrel also showed that an actively immunized rabbit, capable of withstanding large doses of toxin subcutaneously or intravenously, yet succumbs as readily to the intracerebral injection of toxin as a normal rabbit.

It should be noted that Abel (Abel *et al.* 1938, Abel and Chalian 1938) distinguished two stages in the action of toxin—adsorption to the nerve cells, and fixation. Fixation coincided with the appearance of tetanic symptoms. In the

sheep, antitoxin given intravenously after demonstrable absorption of lethal amounts of toxin by the nervous tissue, but before symptoms of descending tetanus had appeared, had a curative action.

Diagnosis.

The bacteriological diagnosis of tetanus is often difficult and sometimes impossible.

Microscopical Examination should be made where possible of the pus in the wound, and special note taken of bacilli with round, terminal spores. The presence of " drumstick " bacilli is *not*, however, pathognomonic of infection with *Cl. tetani*. The organisms may be present in such small numbers that they may be altogether overlooked.

Cultural Methods are of more importance. The pus or wound scrapings are seeded into cooked meat medium, or into heart or liver digest broth containing a small portion of sterile rabbit kidney. After 5 days' anaerobic incubation at 37° C., if the typical bacilli are visible microscopically, the culture is heated to 70–75° C. for 20 minutes to destroy non-sporing bacilli, and plated out on liver or serum agar. To obtain a pure culture repeated platings may be necessary. Fildes (1925*a*) has drawn attention to the rapidly-spreading, effuse, proteus-like growth that occurs on an agar slope if the water of condensation is inoculated; the bacilli grow over the whole slope and present a tenuous, jagged, fern-like edge at the top. From this a subculture may be made into the condensation water of a fresh tube, and a pure culture obtained after two or three transfers. Besides studying the cultural and biochemical reactions of the strain it is well to test it with a polyvalent agglutinating serum prepared against the common serological types of bacilli in the neighbourhood (Fildes 1925*b*). Enrichment of the material for culture in broth containing 1/100,000 crystal violet is said to be effective (Gilles 1937*b*).

Animal Inoculation.—Material from the wound should be suspended in saline and injected subcutaneously into mice or guinea-pigs. Though this procedure may give a positive result, it is not advisable to rely on it exclusively. Every effort should be made to obtain the organisms in pure culture before injection; it is generally agreed that animal inoculation from a pure culture is more likely to be successful than from a mixed culture (McCoy and Bengtson 1918, Tenbroeck and Bauer 1922). The signs of tetanus in an animal are almost unmistakable, but a careful microscopical examination of the wound and the blood should be made to exclude the presence of other organisms. If a pure culture of the bacillus gives rise to the disease, then a broth filtrate should be injected into two mice, one of which has been given a prophylactic dose of antitoxin. In this way the toxicity of the strain can be established.

Prophylaxis and Treatment.

The surgical treatment of wounds that are likely to be followed by tetanus lies outside our province, but clearly everything must be done to avoid the persistence of necrotic tissue, and to control bacterial proliferation within the wound. Attention must be drawn to the desirability of using properly prepared and disinfected catgut in the suturing of tissues at operation. The way to ensure this is described in the admirable monograph by Bulloch (1929) and his collaborators Lampitt and Bushill (1929).

Preparation, Standardization and Properties of Antitoxin.—The **preparation** of tetanus antitoxin, which plays so important a part in the prophylactic treatment of tetanus, has been the subject of research ever since its discovery. The pure toxin is too active to be injected directly into susceptible animals, and some method of decreasing its toxicity has to be employed.

Behring and Kitasato (1890) and Kitasato (1891) found that the injection into rabbits and mice of tetanus toxin, modified by treatment with a solution of iodine tri-chloride, rendered them immune; their serum was found to contain an antitoxin capable of neutralizing the toxin. Later Behring (1892) immunized sheep and horses, and was thus able to obtain antitoxin in considerable quantities. Experiments on mice infected with splinters of wood dipped in a heated broth culture of *Cl. tetani* showed that the antitoxin was capable of protecting them if given before, simultaneously with, or 24 hours after the infection. The therapeutic dose required was very much greater than the prophylactic dose. Thus in one experiment the effective dose of serum was 0·001 ml. when given 15 hours before, 0·1 ml. when given at the same time as, and 0·4 ml. when given 24 hours after, the infection (Kitasato 1892).

Vaillard (1892) confirmed the value of iodized toxin, and succeeded in immunizing rabbits by the injection of successive doses of filtered cultures heated at progressively lower temperatures; finally the animals were able to withstand the intravenous injection of pure toxin. He likewise confirmed Behring's and Kitasato's work on the neutralizing and protective powers of the antitoxin, but was unable to satisfy himself of its curative power (Vaillard 1891). After a dose of 0·5 ml. of antitoxic rabbit serum into a mouse, the animal resisted the injection of toxin during the next few days; but after about a fortnight the passive immunity wore off and the animal regained its susceptibility to toxin. Serum injected some hours after the commencement of symptoms was without effect on the progress of the disease. Tizzoni and Cattani (1891*a*) were also unable to convince themselves of the curative power of antitoxin.

Antitoxin was later produced on a large scale by the injection of horses with toxin-antitoxin mixtures (Buxton and Glenny 1921). The toxin was over-neutralized, and a series of injections was given at intervals of a few days over a period of some months. Of recent years the preliminary treatment of toxin with formol has been widely adopted. The action of the formol is to deprive the toxin of its toxicity, while having little effect on its antigenic value. After a series of initial injections with this formolized product—sometimes referred to as anatoxin or formol toxoid—crude toxin itself can be injected. The actual technique of preparing the toxoid need not detain us here. Usually about 0·4 per cent. of formol is added to the toxin, and the mixture is incubated at 37°–39° C. till it is sufficiently detoxified. About 20 ml. of formolized toxin should prove non-toxic to the guinea-pig on subcutaneous inoculation (Hosoya *et al.* 1931, Wilcox 1934). Some workers precipitate the toxoid with alum or zinc chloride, while some add tapioca or 0·5 per cent. $CaCl_2$ in an endeavour to increase its antigenic efficiency (see Glenny *et al.* 1926, Ramon *et al.* 1931, Ramon and Lemétayer 1932, Bergey 1934).

The **standardization** of tetanus antitoxin has presented considerable difficulties, due in part to the liability of tetanus toxin to deterioration. In the past three different units have been employed—a German, a French, and an American. Comparative observations made under the auspices of the Permanent Committee on Standardization of the Health Organization of the League of Nations showed that the relation of these units was as follows: 1 German unit = 66 American = 3,750 French units (see Prausnitz 1929). It was agreed that an international unit should be established equivalent to one-half the existing American unit, and that the standard antitoxin should be kept at the Serum Institute, Copenhagen. So defined, the unit of tetanus antitoxin represents the specific neutralizing activity for tetanus toxin contained in 0·1547 mgm. of the standard preparation. Antitoxin titrations

are best carried out by the subcutaneous injection of toxin-antitoxin mixtures into mice, and the determination of that amount of toxin which just fails to produce tetanus by the 4th day (L0 dose). The L+ dose, *i.e.*, that dose which kills the animal on the 4th day, is much less satisfactory as a basis for standardization.

Comparative tests in a number of institutions have shown that antitoxins can be assayed with some success provided that one specimen of toxin is employed. The toxic filtrates commonly used for assay, however, vary greatly with the strain of *Cl. tetani* and the medium selected for its growth. Even when the standardization of the toxin, and the methods of administering toxin and antitoxin to a given breed of test animals, have been carried to practicable limits, there are qualitative as well as quantitative differences among antitoxins that may vitiate the assay. (Report 1938, Smith 1938, Ipsen 1940–41.)

The potency of proteolytically refined antitoxins may be measured by flocculation methods analogous to the Ramon titration of diphtheria antitoxin (see, for example, Goldie, Parsons and Bowers 1942).

Properties.—Tetanus antitoxin remains fairly stable in a cold, dark place. If dried, powdered, and preserved in vacuum tubes in the presence of phosphorus pentoxide, and kept in the dark at 5° C., it remains unaltered for years (Rosenau and Anderson 1908). Exposure to sunlight or diffuse daylight gradually destroys it. It resists heat at 60° C. for half an hour, but is partly destroyed at 65° C., and completely at 68° C. (Tizzoni and Cattani 1891*b*). It is non-dialysable, and is precipitated by ammonium sulphate with the globulin fraction. Hydrochloric and lactic acids, and caustic potash, destroy it.

Injected intravenously into animals, antitoxin circulates in the blood for some days. A very small amount may pass into the cerebrospinal fluid and into the milk of lactating animals (von Lingelsheim 1912). After subcutaneous injection the highest titre of antitoxin in the blood is reached in 1 to 3 days; from then on it diminishes till after a fortnight only a trace is left. Injected into the sub-arachnoid space it passes almost completely into the blood stream.

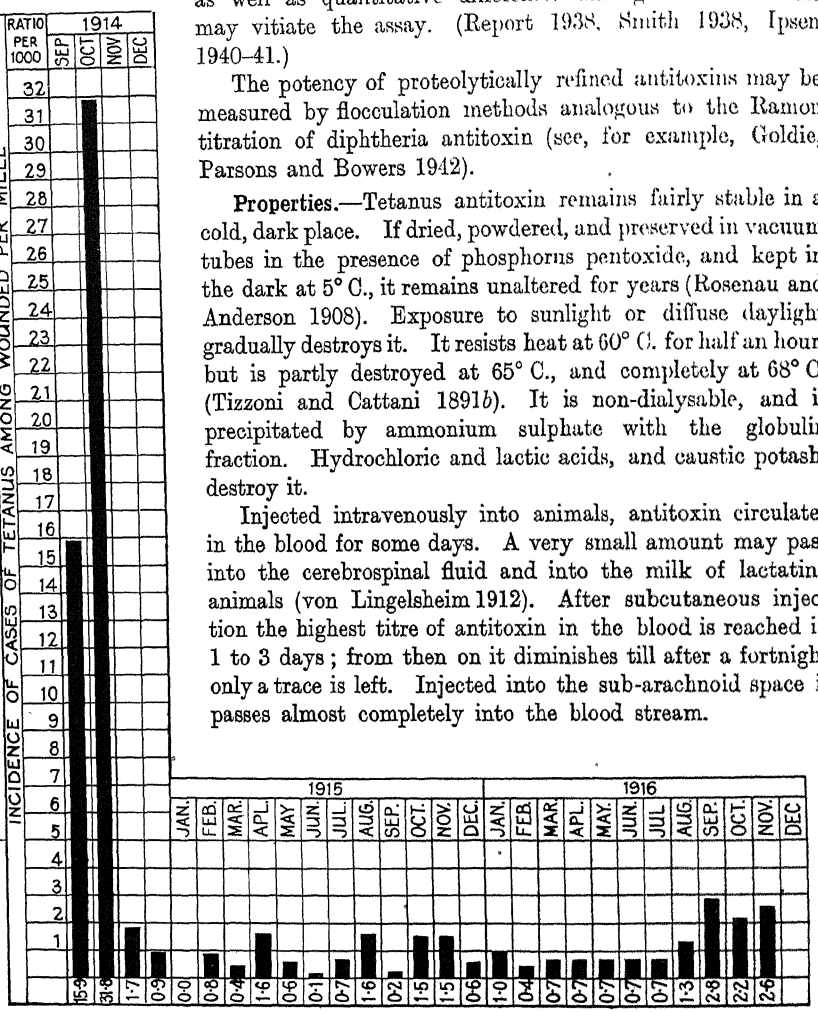

FIG. 295.

The incidence of tetanus per 1,000 wounded in Home Hospitals during 1914–16, showing the fall in incidence after Oct., 1914, when the use of antitetanic serum became generalized. (After Bruce.)

MacConkey and Homer (1917) found that the passive immunity conferred on guinea-pigs by the subcutaneous injection of 3½ units of antitoxin disappeared in about a fortnight. Increased dosage up to 40 units did not prolong this period; but when enormous doses were given—250 to 3,500 units—the animal remained immune for about a month. That is to say, passive immunity is at the best transient, and can be relied upon only for a short time.

Prophylactic Injection of Antitoxin.—In the prophylaxis of tetanus in man it is advisable to inject 500-1,500 units of antitoxin into the subcutaneous tissues as soon as possible after the receipt of the wound. The type that calls for this treatment is the dirty lacerated wound, contaminated with street mud, earth, or animal fæces, especially if accompanied by severe bruising of the tissues or fracture of the bones. It is advisable to inject a portion of the serum in two or three places around the actual lesion. The wound itself should preferably be excised: if this is impossible it should be cleansed and thoroughly drained. If the wound is severe and is likely to take some time to heal, it is well to repeat the injection every week. Should symptoms of tetanus develop, large doses—30,000 units or more must be given every day, partly around the wound and partly intrathecally.

From animal experiments there is not the least doubt of the protective value of antitoxin, but in man the evidence is necessarily indirect. This may be summarized as follows:

(1). The prophylactic injection of antitoxin within a few hours of the receipt of a wound appears to diminish greatly the chances of tetanus. The incidence during the war of 1914-18 is recorded in Figs. 294 and 295. The sudden fall in November, 1914, can in all probability be ascribed to the prophylactic use of antitetanic serum that was introduced about the middle of the preceding month. The rise towards the end of 1916 may have been fictitious; Bruce ascribes it to improved diagnosis, particularly of local tetanus, which was largely overlooked at the beginning of the war. The subsequent fall in 1917 and 1918 may perhaps be related to the more efficient prophylactic serum treatment which was commenced in June, 1917, but more probably to the practice of early excision of wounds which was introduced about the same time.

(2) When it does not prevent the development of tetanus it appears to lengthen its incubation period. This will be seen from Table 171, showing the average incubation period amongst wounded treated in home hospitals during the war.

TABLE 171

SHOWING THE AVERAGE INCUBATION PERIOD OF TETANUS IN DIFFERENT YEARS OF THE WAR.

Year.	Length of Incubation Period in Days.
1914	11·8
1915	27·3
1916	34·0
1917	48·0
1918–19	59·0

A direct comparison of the average incubation period in patients who have received, and those who have not received, a prophylactic injection of antitoxin after having been wounded leads to the same conclusion; in the inoculated this period is 45·5 days, in the uninoculated 10·9 days. In this connection it must be remembered that the passive

immunity conferred by a single injection of antitoxin wears off in about a fortnight or three weeks. During this period the patient is unlikely to develop tetanus. But once this is past, he is probably just as susceptible as a person who has never been inoculated at all. Hence if tetanus bacilli are still present in the wound, they are liable to give rise to disease. If all patients had been given repeated doses of antitoxin at intervals of a week till their wounds healed, it is possible that these late cases of tetanus would have been greatly reduced in number.

(3) Tetanus developing in persons who have received a prophylactic injection appears to be less fatal than in uninoculated persons (Bruce 1920). This is seen from Table 172.

TABLE 172

SHOWING THE MORTALITY OF TETANUS IN INOCULATED AND UNINOCULATED PATIENTS.

	No. of Cases.	Died.	Case Mortality.
			Per cent.
Inoculated.	899	203	22·6
Non-inoculated or unrecorded	559	298	53·3

It is interesting to note that the average mortality amongst the inoculated during the war fell far more rapidly than amongst the uninoculated. This can probably be accounted for by the more regular administration of serum, and by its repeated administration every 7 days for 4 weeks which was undertaken at the instigation of the Tetanus Committee in June, 1917.

(4) During the war the proportion of cases of local to general tetanus rose considerably (Bruce 1920) (Table 173).

TABLE 173

SHOWING THE PROPORTION OF CASES OF LOCAL AND GENERAL TETANUS.

	Percentages.				
	1914.	1915.	1916.	1917.	1918.
General	98·9	98·6	87·0	76·6	83·5
Local	1·1	1·4	13·0	23·4	16·5

This may be in part attributed to the more general and efficient use of antitoxin prophylactically, and partly to improved diagnosis of local tetanus.

Later records of effective antitoxin prophylaxis are scanty and can be considered as no more than suggestive. Thus Wildegans (1940) observed in the Polish campaign of 1939 that the incidence of tetanus among Polish soldiers, over half of whom had received no prophylactic antitoxin, was 66/10,000, as compared with one of 3·6/10,000 in the German soldiers, the majority of whom had been immunized.

Therapeutic Injection of Antitoxin.—Whether or not antitoxin is of any value in man when given subsequently to the development of tetanus is a question that has received no definite answer. The figures collected during the war of 1914–18 were ambiguous, and we see no purpose in retailing them; for their examination the reader is referred to Bruce (1915, 1916, 1917*a*, *b*, *c*, *d*, 1919), Dean (1917), and Leishman and Smallman (1917). Experiments with the smaller animals have shown that it is difficult or impossible to interfere with the progress of the disease once

the first symptoms have manifested themselves, unless enormous doses are given; even then the issue is uncertain.

On monkeys, however—chiefly *Macacus rhesus* and *Callithrix*—Sherrington (1917) obtained perfectly unequivocal results. He injected batches of 25 with 8 M.L.D. of toxin into the outer head of the gastrocnemius muscle. From 47 to 78 hours later, when the early symptoms of tetanus had appeared, he injected 2,000 U.S.A. units of antitoxin per kilo of monkey, giving the serum by different routes to the separate batches. All the control animals receiving no antitoxin died; the mortality amongst the inoculated was as follows (Table 174).

This experiment answered two questions. It showed first of all that antitoxin might be of considerable therapeutic value; and secondly that the route by which it was given was of supreme importance. Whereas antitoxin administered subcutaneously or intramuscularly had but little effect, given intrathecally it saved the lives of over half the animals.

TABLE 174

Serum given by:	Deaths.	Recoveries.	Percentage Mortality.
			Per cent.
Subcutaneous route	23	2	92
Intramuscular route	22	3	88
Intravenous route	18	7	72
Lumbar intrathecal route . .	11	14	44
Bulbar intrathecal route. . .	7	13	35
Cerebral subdural route . . .	10	0	100

It is difficult to explain the discrepancy between Sherrington's experimental results and the results in clinical practice; but two points may be noticed. Firstly the monkeys were injected with pure toxin, not with bacilli; it is doubtful whether the results would have been so favourable if an active infection had been set up. Secondly the dose of antitoxin used was large 2,000 units per kilo of monkey. This corresponds in man to 120,000 units administered in a single dose. To give this, using a highly potent serum containing 800 units per ml., would necessitate the injection of 150 ml.—an amount far in excess of that which could be administered intrathecally at one time. The average daily dose given in human practice often by two or three routes—has been from 1,000 to 30,000 units; larger doses have not often been employed. If the quantities suggested by Sherrington's work are really necessary—and experience suggests that smaller doses are inadequate—then it would seem desirable to devote attention to the production of more potent antitoxic sera than those which we now possess.

Firor (1940) obtained similar results to those of Sherrington in dogs given 2 M.L.D. of toxin. Intrathecal antitoxin by the cisternal route saved 51 of 70 dogs (73 per cent.), by the lumbar route 19 of 30 dogs (63 per cent.), whereas intravenous antitoxin saved only 5 of 20 dogs (25 per cent.).

The conclusion from this experimental work (see also Friedemann, Hollander and Tarlov 1941) finds some support in the experience of clinical observers who have succeeded in curing severe tetanus by the use of very large doses of antiserum, sometimes administered by the cisterna magna (see Paterson 1930, O'Carroll 1931, Bell 1931, Nabarro 1932). Nabarro, for example, injected no fewer than 633,000 units of antitoxin within the space of 9 days, while Paterson used nearly 2 million units.

Even more suggestive, however, are the figures reported by Yodh (1932) at the J.J. Hospital in Bombay. Before he took charge, tetanus patients were treated with sedatives, and were given antitoxin intravenously and intramuscularly in doses of about 20,000 units a day. After taking charge, Yodh continued this treatment for a time, using, however, slightly larger doses of sedatives and serum. Later, he increased the dose of antitoxin a little more, and injected part of it by the lumbar intrathecal route. Still dissatisfied with his results, he started giving serum intrathecally by the cisterna magna, as well as intravenously, intramuscularly, and subcutaneously around the wound. Usually only one cisternal injection was made, 20–30 ml. of serum being injected. The total amount of serum administered to any given patient varied from 40,000 to over 400,000 units. The results are given in Table 175.

The cases were not strictly consecutive. Of a total of 229 cases treated by Yodh himself, 15 were not given serum treatment for one reason or another, sometimes because they were moribund. Since the distribution of these cases in point of time is not stated, it is impossible to know how much allowance to make on the figures yielded by the serum-treated patients. The results, however, do suggest very strongly that the intrathecal administration of serum by the cisterna magna route

TABLE 175

EFFECT OF ROUTE AND DOSE OF SERUM INJECTIONS IN HUMAN PATIENTS SUFFERING FROM TETANUS (Yodh 1932).

Mode of Serum Treatment.	No. of Patients.	No. died.	Case mortality per cent.
20,000 units per diem by *im.* and *iv.* routes . .	49	38	77·6
30,000–40,000 units for 1st day, 20,000 units later, by *im.* and *iv.* routes	80	52	65·0
Larger doses of serum by *im.*, *iv.*, and lumbar intrathecal routes	22	14	63·6
Total of 40,000 to 400,000 units by *im.*, *iv.*, *sc.*, and cisterna magna routes	112	53	47·3

im. = intramuscular: *iv.* = intravenous: *sc.* = subcutaneous.

is definitely beneficial. Clinically, some improvement was generally noticeable within 24 hours of the cisterna injection.

From Sherrington's results on monkeys and Yodh's results on human beings, it would appear that intrathecal administration of serum is more beneficial than injection by any other route. Why this should be so, it is difficult to understand. On *a priori* grounds one would expect that antitoxin conveyed by the blood stream would come into more intimate contact with the affected nerve cells than when it was injected into the cerebrospinal fluid. The superiority of the intrathecal route is, however, not yet completely substantiated. Florey and Fildes (1927), for example, obtained no better results in the therapeutic treatment of rabbits by the intrathecal than by the intravenous method. Moreover, Paterson (1930), who treated 26 consecutive children suffering from tetanus with only 7 deaths, used the intravenous and intramuscular routes. It must be noted, however, that Florey and Fildes' experiments were carried out on so few animals that a small advantage possessed by the intrathecal route may quite well have been obscured, while Paterson used

enormous doses of serum, varying from a total of 120,000 to one of 1,970,000 units. Others have strongly deprecated the intrathecal route on the ground that antitoxin may be a severe irritant, and that the ensuing inflammatory reaction may do more harm than the antibody does good (see, for example, Wainwright 1926, Spaeth 1941).

If we accept the view that tetanus toxin is irrevocably fixed to nervous tissue by the time tetanus is manifest, the therapeutic effect of toxin will be limited to the neutralization of toxin in the blood, lymph and tissue fluids, and of toxin as it is absorbed from the local lesion.

The experiments of Abel and others (1938) suggest that, in addition to toxin already fixed by the nerve tissue, some will be adsorbed but not "fixed" to other nerve tissue, and in these circumstances can be neutralized by antitoxin. Therapy should, therefore, be directed to maintaining an effective concentration of antitoxin in both the circulation and the central nervous system. Large doses of antitoxin have been recommended. Aside from their reported success, these have a theoretical justification, for the action of toxin on the capillary endothelium seems relatively slight, and consequently does not induce a ready permeability to circulating antibody. The presence of high concentrations in the blood may ensure that, even with a low degree of capillary permeability, the antitoxin content of extravascular intoxicated tissue may be raised to a therapeutically effective level.

Summarizing, the evidence indicates that in the therapeutic treatment of tetanus large and repeated doses of serum are required. In practice it seems advisable to administer the serum by the intramuscular, intravenous, and intrathecal routes. There is evidence that injection into the cisterna magna is of more benefit than by the lumbar puncture route.

Active Immunization.

Since the demonstration of the antitoxinogenic value of toxoid (formaldehyde-treated toxin; Descombey 1924) and alum-precipitated toxoid (Bergey 1934, Jones and Moss 1936), these agents have been widely tested in man. Owing to the low incidence of tetanus in peace-time, the efficacy of active immunization has been for the most part judged by the antitoxin response in the inoculated subject, and it is only in the last few years that indications of its prophylactic value have been obtained.

There is little doubt that the injection of two to three doses of toxoid at properly spaced intervals raises the antitoxin content of the blood within a few months to the level usually obtained by the injection of a prophylactic dose of antitoxin; and there is good reason to suppose that a given blood level indicates a far higher degree of immunity in the actively, than in the passively immunized person. Thus d'Antona and Valensin (1937) found that actively immunized guinea-pigs with blood levels of 0·012 to 0·05 A.U. per ml. withstood 200 M.L.D. of toxin, while passively immunized animals with 0·2 to 0·5 A.U. per ml. either died or developed severe local tetanus (see also Sneath, Kerslake and Scruby 1937). The difference may in part be due to a better distribution of antitoxin in the actively immunized animal and to the rapid production of antitoxin in an animal conditioned by the previous antigenic stimulus. That the antibody-forming apparatus is conditioned in this manner is clear from the results of injecting toxoid some months after the primary series of injections. Not only is the antitoxin content raised to higher levels than the maxima achieved after the previous injections, but the levels are maintained for longer periods. The response to this secondary, stimulating dose is very striking; the antitoxin content of the blood rises rapidly, and an average titre of over 10 A.U. per ml. is often reached—more than 100 times as high as that following the primary series of inoculations.

In practice, the interval between the primary and secondary doses is usually 3–12 months, but there is some evidence (see Regamey 1944) that the response is even greater after a lapse of 2–3 years. It should be noted that there are great individual variations in response, both to the primary and secondary injections (see Ramon and Zoeller 1933, Sacquepée and Jude 1937, Boyd 1938, Marvell and Parish 1940, Prigge 1940, Evans 1941, 1943, Peshkin 1941, 1944, Fraser *et al.* 1943).

It is administratively convenient to mix toxoid with enteric vaccines. The response to toxoid is reported by some to be enhanced by the presence of vaccine, by others to be unaffected (see, for example, Maclean and Holt 1940, Regamey 1944, and Chapter 50).

Mass immunization is practised mainly in the fighting services. The procedure varies to some extent. Boyd (1938), aiming at a minimum level of 0·01 A.U. per ml., recommends two doses of 1 ml. of toxoid at an interval of 6 weeks, followed by a stimulating dose 9 months later. In the American Army three doses of 1 ml. are given at intervals of three weeks, followed by a fourth dose 1 year later or before military operations (Long 1943).

The efficacy of Boyd's method of immunization was substantiated by the absence of tetanus among immunized soldiers of the British Expeditionary Force in France 1940. Although a large proportion of them failed to receive a prophylactic dose of antitoxin upon wounding no case occurred in over 16,000 actively immunized men, whereas 8 cases occurred in 1,800 men who had not been immunized (Bensted 1940). During the years 1940–42 of the North African campaign, the incidence of tetanus was 0·13 per 1,000 wounded in the actively immunized, 1·6 per 1,000 wounded in the non-immunized (Boyd and MacLennan 1942). Of the 18 patients with tetanus in Boyd and MacLennan's series, only three were known to have received the routine prophylactic dose of antitoxin after wounding; in 5 there was no record, but the remaining 10 had had none. The protection afforded by active immunization was clearly not complete, for 5 cases, 3 of them fatal, occurred in the immunized group. In one of the fatal cases, the evidence suggested a poor antibody response to the toxoid. The possibility of a poor response to primary injections of toxoid emphasizes the need, not only for a secondary stimulating dose during routine immunization, but also for passive immunization on wounding.

It is the practice in the French and American armies to enhance immunity at the time of wounding by a stimulating dose of toxoid. This method has the advantage over serum prophylaxis that toxoid keeps better than antitoxin and is, therefore, simpler to use in the field, and that it does not lay the foundation of a serum-hypersensitiveness. The antibody response to its injection is, however, relatively slow, taking from 2–5 days to develop; and though the average incubation period of tetanus is about 7 days, the more severe infections, in which prophylaxis is of prime importance, develop as a rule more rapidly, before in fact the antitoxin response is manifest. Moreover, aside from a natural insusceptibility to active immunization that characterizes a small proportion of human subjects, the presence of shock, fatigue, cold, and malnutrition in the wounded man may inhibit the antibody response.

Zuger, Greenwald and Gerber (1942) record that immunization with toxoid protected a high proportion of guinea-pigs against a lethal dose of tetanus spores given several months later. When a stimulating dose of toxoid was injected at the time of infection, the protection rate was higher but the active immunity achieved was not solid; some of the guinea-pigs developed local tetanus.

On *a priori* grounds it might be best to give severely wounded patients combined active and passive immunization as soon after receipt of the injury as possible,

so as to ensure protection against rapidly fatal tetanus during the lag phase elapsing between the giving of the secondary stimulating dose of toxoid and the active formation of antitoxin. (For combined immunization with antitoxin and toxoid, see Chapter 50).

The standardization of tetanus toxoid for use in man is based on the antigenic response in guinea-pigs. British regulations for instance require that more than 9 guinea-pigs must be injected with five times the human dose, and that after 6 weeks, at least two-thirds of the guinea-pigs must contain at least 0·1 A.U. per ml. of blood serum.

The Lf value of a toxoid preparation is not a reliable guide to its antigenicity (see, for example, Glenny and Stevens 1938, Lahiri 1940, Koerber 1943, Moloney and Hennessy 1944). On the ground that the antitoxin levels in the serum of an immunized guinea-pig are not a full measure of active immunity, Istrati, Kicksch and Prigge (1940) recommended a protection test, in which the resistance of immunized and normal animals to a standard dose of toxin is compared. Mouse protection tests on these lines have also been devised (see Lahiri 1942, Greenberg, Morrell and Gibbard 1943, Koerber and Mook 1943).

Tetanus in Animals.

The natural disease attacks horses more frequently than other animals, and is especially common in warm and tropical countries. In Northern Europe the incidence is low; thus in the years 1899–1908 in the Prussian Army the annual average of horses developing the disease was only 0·6 per 1,000 (Hutyra and Marek 1912).

Tetanus occurs less frequently in cattle, sheep and goats, though it is not uncommon in ewes after parturition and in lambs after docking; it is uncommon in the pig and the dog.

Infection occurs by contamination of wounds of skin, or of raw surfaces; nails in the hoof, castration, tail docking, harness galling, bone fractures, and imperfect treatment of the navel at birth, seem to be responsible for the majority of cases.

Prophylactic injection of antitoxin is recommended previous to operations on the horse. Nocard (see Mohler and Eichhorn 1911) reported that in 2,727 horses which were given serum after various operations not a single case of tetanus developed, whereas during the same period 259 cases developed in horses that were not inoculated (number not stated). As a rule 500 units is sufficient. The passive immunity so conveyed lasts longer in the horse than in other animals because the serum is homologous, and is therefore excreted more slowly (Mohler and Eichhorn 1911). Buxton and Glenny (1921) were able to render horses actively immune by 3 injections at intervals of 3 days of a toxin-antitoxin mixture. A month later the animals withstood 2,000 guinea-pig M.L.D. of crude toxin. They recommend this method for the immunization of army horses (see also Glenny, Hamp and Stevens 1932).

Therapeutic injection of serum has not been followed by satisfactory results (Mohler and Eichhorn 1911).

CHAPTER 78

GAS GANGRENE: ANAEROBIC INFECTIONS OF ANIMALS

GAS GANGRENE IN MAN

In the pre-antiseptic days the formation of sloughs, the occurrence of massive necrosis, and the onset of gangrene, so frequently followed upon any extensive operative procedure that they were regarded as more or less inevitable features of surgical practice. With the advent of antiseptic surgery, and the consequent healing of wounds by first intention, these processes became less and less common, till eventually even the names by which they were described took on an archaic air. It was therefore not unnatural that when gas gangrene appeared in the early days of the war of 1914–18, many surgeons were confronted with it for the first time. It was the older surgeons, who had had experience of pre-Listerian methods, who recognized its true nature, and who pointed out the impossibility of preventing it by the modern aseptic methods. Nevertheless, though the disease was old, its study had to be taken up anew. The problems involved were attacked with such success that by the end of the war gas gangrene had ceased to be of more than minor importance. In peace time the disease is uncommon, but is occasionally met with after severe compound fractures, and during the puerperium, particularly when following illegal abortions (see Hill 1936).

In this chapter we can give only an outline of the bacteriological investigation of gas gangrene; for a full description the reader is referred to the monograph of Weinberg and Séguin (1918), and to the Report of the Anaerobic Committee (see Report 1919).

Bacteriology.—In 1914 the incidence of gas gangrene amongst the British Expeditionary Force amounted to over 12 per cent. of the number wounded; of these 20–25 per cent. died. By 1918, owing to earlier evacuation of the wounded, excision of wounds, the employment of an antiseptic technique, and other measures, the incidence had fallen to under 1 per cent. (Report 1919). Indeed, in the Base Hospitals in 1918, amongst a total of about 25,000 wounded reported on by Bowlby (1919), only 84 patients developed serious or massive gas gangrene—an incidence of 0·34 per cent. In the French and German armies the incidence appears to have been rather higher.

Examination of the wound of a man dying of gas gangrene revealed a number of organisms, aerobic and anaerobic; it was uncommon to meet with only one species of bacterium. Thus in an examination of 91 cases, Weinberg and Séguin (1918) found anaerobes in 24, and anaerobes plus aerobes in 67; in only 10 of the former group was a single species isolated—monomicrobial infection. The diversity of flora was so great that no fewer than 38 different combinations of anaerobic bacteria occurred in their 91 cases. To separate these different organisms

and to estimate their particular rôle in the genesis of the disease was a heavy task; the results obtained by the French and English workers, however, agreed sufficiently well for it to be possible to state definitely that certain anaerobes, alone or in combination, were primarily responsible for gas gangrene (Table 176).

TABLE 176

THE FREQUENCY OF DIFFERENT ANAEROBES IN GAS GANGRENE (Report 1919).

	Weinberg and Séguin.	McIntosh.	McIntosh.	Henry.
	91 Cases.	41 Cases.	52 Cases.	50 Cases.
	Per cent.	Per cent.	Per cent.	Per cent.
Cl. welchii (*B. perfringens*)	77	43·9	67·3	80
Cl. œdematiens	34	—	4·0	10
Cl. sporogenes	27	36·5	38·7	—
Cl. fallax	16·5	—	—	6
Cl. septicum	13	19·5	16·3	16

Numerous other anaerobic bacilli were also found, such as *Cl. histolyticum*, *Cl. aerofœtidum*, *Cl. putrificum*, *Cl. bifermentans*, and *Cl. tertium*. Of the aerobes commonly encountered the majority consisted of diplo-streptococci and organisms belonging to the *Proteus* group (Weinberg and Séguin 1918). In 37 of Weinberg and Séguin's cases only one species of anaerobe was isolated; of these 29 were *Cl. welchii*, 5 *Cl. œdematiens*, 1 *Cl. septicum*, 1 *Cl. fallax*, and 1 *Cl. aerofœtidum*.

The suggestion that each of these organisms was capable by itself of giving rise to gas gangrene was borne out by animal experiments. With the possible exception of *Cl. sporogenes*, these five organisms were the only ones that could reproduce in animals a disease simulating the condition in man. With regard to *Cl. sporogenes* it is not clear whether it is pathogenic by itself. The work of the English bacteriologists suggested that it played a subsidiary but important rôle in assisting *Cl. welchii*, *Cl. œdematiens*, and *Cl. septicum* in their attack on the tissues, but that by itself it is harmless. On the other hand, Weinberg and Séguin regarded it as potentially though weakly pathogenic.

From his study of wound infection in the British Army campaigns in North Africa, 1940 to 1942, MacLennan (1943, 1944*a*) recognized three clinical conditions associated with clostridia, namely, simple contamination which occurred at some stage in the history of 20–30 per cent. of all the wounds examined, "anaerobic cellulitis" developing in about 5 per cent. of contaminated wounds, and "clostridial myositis," the true gas gangrene, developing in about 1·5 per cent. of wounds containing anaerobes, and in about 0·34 per cent. of all wounds.

The clostridia most frequent in 259 contaminated wounds were *Cl. tertium* (46·7 per cent.), *Cl. butyricum* (34·3 per cent.), *Cl. welchii* (23·5 per cent.) and *Cl. sporogenes* (20·1 per cent.). Unidentified clostridia were present in 13·2 per cent.; the incidence of *Cl. œdematiens* was 5·8 per cent., and no *Cl. septicum* was found. In anaerobic cellulitis, characterized by foul, sero-purulent infection of the depths and crevices of the wound, without progressive involvement of muscle, the predominant organisms were proteolytic and non-toxigenic clostridia, and *Cl. welchii*. In 146 cases of true gas gangrene, the pathogenic clostridia were as follows: *Cl. welchii* (57 per cent.), *Cl. œdematiens* (37·7 per cent.), *Cl. septicum* (20·0 per cent.), *Cl. tetani* (13·1 per cent.), *Cl. histolyticum* (6·9 per cent.), *Cl. bifermentans* (4·8 per cent.) and *Cl. fallax* (1·4 per cent.). As the fighting moved from desert to more cultivated country, the incidence of gas gangrene was doubled and the

percentage of *Cl. welchii* infection increased. The frequency of the pathogenic clostridia when they were present singly in wounds was as follows: *Cl. welchii* 34·3 per cent., *Cl. œdematiens* 17·1 per cent., *Cl. septicum* 4·8 per cent., *Cl. histolyticum* and *Cl. bifermentans*, each 0·7 per cent. In other cases more than one species was isolated. Anaerobic streptococci (see Chapter 67) were found in 8·8 per cent. of cases.

Summing up, we may say that gas gangrene may be caused by a number of different anaerobic bacteria, usually clostridia, but sometimes by anaerobic streptococci. Usually the clostridia are present either in combination with each other or with aerobic organisms. The three most important anaerobes are *Cl. welchii* (*B. perfringens*), *Cl. œdematiens*, and *Cl. septicum* (*Vibrion septique*); of less importance are *Cl. bifermentans*, *Cl. fallax*, *Cl. histolyticum*, and *Cl. sporogenes*. The presence of pathogenic clostridia in a wound, however, is not necessarily indicative of a gas gangrene infection. Most commonly they appear to be simple contaminants of wounded tissues; they are frequently associated with cellulitis, and only infrequently with true gas gangrene.

Reproduction of Gas Gangrene in Animals.

The experimental disease caused by *Cl. welchii*, *Cl. septicum*, and *Cl. œdematiens* has already been described in Chapter 36.

Each of these organisms, it will be remembered, forms true exotoxins (Bull and Pritchett 1917*a*, *b*, Report 1919, Weinberg and Séguin 1918), which apparently possess hæmolytic, leucocidal, and necrotic powers (Kamen 1904, Eisenberg 1907, Simonds 1915, Weinberg and Séguin 1918, Report 1919, Weinberg and Ginsbourg 1927). The most potent toxin is formed by *Cl. œdematiens*; indeed the disease associated with this organism partakes more of an intoxication than a true infection.

Mode of Development of Gas Gangrene in Man.

We have already seen that the injection of a broth culture of *Cl. welchii* or *Cl. septicum* into a guinea-pig will give rise to a disease simulating gas gangrene. If, instead of using a whole broth culture, we wash the organisms thoroughly to free them from toxin, no disease is set up. Likewise, saline suspensions washed off an agar slope are non-pathogenic. Large numbers of the bacilli can be injected without giving rise even to a local lesion. But if to the toxin-free bacilli a sub-lethal dose of toxin (broth filtrate) is added, the mixture proves intensely virulent. A protocol from De Kruif and Bollman's paper (1917) will illustrate this point:

Effect of intramuscular injection into guinea-pigs of—

1·0 ml. *Cl. welchii* broth filtrate	Survived.
0·05 ml. washed organisms + 0·5 ml. sterile broth . .	Survived.
0·1 ml. „ „ + 0·5 ml. „ „ . .	Died 36 hrs.
0·000,01 ml. „ „ + 0·5 ml. broth filtrate . .	Died 19 hrs.

It will be seen that a non-lethal dose of filtrate decreased the M.L.D. of the washed bacilli several thousand times.

The broth filtrate contains an aggressin which enables the bacilli to proliferate in the tissues. Without this the bacilli are partly lysed by the tissue fluids and partly taken up by phagocytes; with it neither lysis nor phagocytosis occurs, but the organisms divide, produce fresh toxin, and bring about the death of the

animal. The aggressin is probably the α-toxin, for its action can be completely inhibited by specific antitoxin (see Stewart 1943*a*). Of the toxic components in culture-filtrates of *Cl. welchii* Type A, antibodies to the α- and θ-toxins and to the hyaluronidase (see Chapter 41) are present in preparations of antitoxin, and of these, only the antitoxin has protective properties (Evans 1943*a*, *b*). In other words, the bacilli apart from their toxin are powerless to overcome the resistance of the tissues. How the broth filtrate acts is not clear, but since both *Cl. welchii* and *Cl. septicum* are known to bring about in culture a very steep fall in Eh, it is possible that the filtrate contains reducing substances capable of establishing a sufficiently low O-R potential to enable the spores to germinate; or that the tissues themselves develop a low O-R potential as a result of intoxication. Once germination has started, the organisms probably produce their own reducing system, which enables them to multiply even in the presence of healthy tissue.

Toxin is not the only substance, however, that can break down this resistance. Bullock (Gye) and Cramer (1919), whose work has been described in the last chapter, found that small quantities of ionizable calcium salts—notably calcium chloride—exerted a similar kataphylactic action. Colloidal silicic acid behaved in the same manner.

Since the organisms introduced into a wound are devoid of toxin, being frequently in the sporing stage, their germination must depend on other factors. In the opinion of Bullock and Cramer the determining factor is some kataphylactic substance that is carried into the wound with them. Earth containing calcium salts or silicic acid is suggested as the probable accessory agent. The work of Fildes (1927) and Russell (1927) renders it highly probable that such substances as earth or calcium chloride act by causing foci of necrosis, in which the oxidation-reduction potential becomes sufficiently reduced to enable the anaerobic bacterial spores to germinate (see Chapter 77). Fragments of clothes in the wound also appear to act as foci for the germination of spores. The observation of Fildes (1935) that in fluid media cellulose fibres induce an O-R potential low enough to permit the germination of tetanus spores is clearly relevant in this connection.

The possible importance of secondary infection is difficult to assess; it may well be that highly proteolytic organisms such as *Cl. histolyticum*, *Cl. putrificum*, *Cl. bifermentans*, and *Proteus vulgaris* assist in preparing the way for the gas-gangrene bacteria, not only by destroying the tissues, but by lowering the O-R potential to the critical level for germination (see Hewitt 1936). Bacteria like certain staphylococci and streptococci, as McClean and Rogers (1944) suggest, may promote the spread of the gas-gangrene organisms by releasing hyaluronidase into the tissues of the wound. Similarly mechanical injury, crushing of the tissues, effusion of blood, and fracture of bone may have the same effect. But of the precise effect of each of these agents we are entirely ignorant.

That some determining factor is necessary, however, is shown not only experimentally in animals, but by the observation in man that *Cl. welchii*, *Cl. septicum* and *Cl. œdematiens* may all be present in a wound without setting up gas gangrene.

Working with *Cl. welchii* Robertson and Keppie (1941), Keppie and Robertson (1944) found that the *in vitro* α-toxigenic capacity was in general highest in gas-gangrene strains, less in those from cases of "anaerobic infections," and least in contaminating wound strains. There were, nevertheless, marked exceptions, and they considered that almost all the strains studied were capable of inciting gas gangrene in suitable circumstances. The toxins of *Cl. welchii* have also been credited with other specific actions, especially

upon the heart (see Nicholson 1934–5, Kellaway, Trethewie and Turner 1940), but the relation of results obtained with "acute" physiological experiments to the syndrome observed in human gas gangrene is not clear. Nor is it known whether the α-toxin owes its toxicity to its lecithinase activity (see Chapter 36), though it is clearly possible that the disruption of lipo-protein complexes in the body may have far-reaching effects on the metabolism of the cells containing them.

"The disease begins, not when a wound has become infected with the pathogenic anaerobes, but from the moment when a group of these bacteria have been enabled to surround themselves with a toxin sufficiently concentrated to abolish the local defences of the tissues" (Report 1919). Once this has occurred, the organisms multiply, produce more toxin, and rapidly invade the tissues. Aside from their aggressive action in the infected tissues, we are largely ignorant of the mode of action of the various clostridial toxins in man. The toxin of *Cl. welchii* has a deleterious action on the suprarenals, and it is partly owing to the consequent lack of adrenalin in the blood that exhaustion and death occur so quickly. This paralysis of the suprarenals is apparently aided by hæmorrhage, exposure to cold, and absorption of the substances formed by growth of the bacilli in the tissues.

Diagnosis.

It cannot be too strongly emphasized that the diagnosis of gas gangrene must primarily be made upon clinical grounds. As the figures on p. 1771 show, the demonstration of one of the pathogenic clostridia in a wound, and especially of *Cl. welchii*, is by itself of little pathognomonic significance. The technique of anaerobic bacteriology is at present too laborious and time-consuming to permit much in the way of confirmatory evidence that will be of value in a disease whose incubation period may be as short as 4 hours, and is on the average 1–2 days. Direct examination, however, of the wound material may yield valuable information, especially for the diagnosis of streptococcal myositis, and should never be omitted (see Memorandum 1943, Hayward 1945).

McClean and his colleagues (McClean, Rogers and Williams 1943, McClean and Rogers 1943, 1944) noted the production of large quantities of hyaluronidase in the gangrenous lesions of guinea-pigs infected with *Cl. welchii*, *Cl. septicum* and with some strains of *Cl. œdematiens*, and devised a simple technique for its rapid recognition in wound exudates, the various hyaluronidases being identified by inhibition with specific anti-hyaluronidase sera. Owing to the frequent presence of hyaluronidase-producing *Str. pyogenes* and *Staph. aureus* in wounds, antisera against the enzymes of these organisms were included in the test. Using this method, MacLennan (1944*b*) obtained only 3 positive results in 12 cases of proved gas gangrene of man—a result which has been attributed to destruction of hyaluronidase by other bacteria in the wound, or its neutralization by mixed antitoxin (see below) given prophylactically to the wounded soldier. The method is noteworthy as providing a possible means of making a presumptive bacteriological diagnosis within an hour of examining a wound.

A full bacteriological examination of a wound should include direct plating, and seeding into media containing cooked meat, thioglycollic acid (Brewer 1940) or other reducing substances that promote anaerobic conditions. The cooked meat culture is plated at intervals to detect the scanty or slow-growing bacilli. The tendency of clostridia to form spreading colonies on the surface of solid media may be counteracted by the use of nutrient gels containing up to 8 per cent. of agar devised by Hayward (Miles and Hayward 1943), which permit the ready isolation of pure cultures. After incubation fluid cultures may

be heated to 80° C. for 20 minutes to destroy non-sporing forms before seeding on to plates. By greater degrees of heating, species with more resistant spores, like *Cl. œdematiens*, may often be obtained in pure culture. *Cl. welchii* and *Cl. bifermentans* may be readily recognized by the Nagler reaction (see Chapter 34) in primary plate culture on a medium containing 20 per cent. human serum. Lecithinase activity of these two organisms produces an opacity in the medium, but none in similar medium containing *Cl. welchii* antitoxin (Hayward 1943).

Pathogenic may be separated from non-pathogenic organisms by animal inoculation. Moreover the individual species of pathogenic bacteria may be separated by injection into protected animals. Thus, if a mixture of *Cl. welchii*, *Cl. septicum*, and *Cl. œdematiens* is inoculated into a guinea-pig that has received a dose of antiserum prepared against the latter two organisms, then *Cl. welchii* alone will proliferate and invade the blood stream. In the absence of laboratory animals, serologically controlled tests of specific hæmolysin production may be used to identify *Cl. welchii*, *Cl. septicum* and *Cl. œdematiens* (Hayward 1945). For a full description of the methods of isolation and purification of the anaerobes the reader is referred to Report (1919) and Hayward (1945).

Blood cultures during life are frequently positive (Weinberg and Séguin 1918). *Cl. welchii* and *Cl. septicum* are especially liable to invade the blood; *Cl. œdematiens*, which acts chiefly by virtue of its toxin, often remains confined to the local lesion.

Prophylaxis and Treatment.

Passive Immunization.—Towards the end of the war of 1914–18, antitoxic and antibacterial sera were prepared against *Cl. welchii*, *Cl. œdematiens* and *Cl. septicum*. No extensive trial was possible, but the results of prophylaxis in a small series of badly wounded soldiers, and of treatment in a number of soldiers suffering from gas gangrene, with mixtures of these sera suggested that both procedures were beneficial (Weinberg and Séguin 1918, Report 1919).

In experimental gas gangrene, both antitoxins and antibacterial sera containing O antibody are protective. But since none of the chief gas-gangrene clostridia is antigenically homogeneous, the efficacy of an antibacterial serum is confined to infections with a given serological type (see Robertson and Felix 1930, Henderson 1934, 1935). It is clearly impracticable to maintain antibacterial sera specific for the multiplicity of serological types. On the other hand the toxic antigens in culture filtrates of these clostridia, though they vary in the content of different components, are to a large extent species-specific, and for routine therapy a mixture of antitoxins can therefore be used.

Several different methods have been employed in the *standardization* of antiserum against gas gangrene (see Dalling *et al.* 1928, Buttle and Trevan 1928, Glenny, Llewellyn-Jones, and Mason 1931, Weinberg, Davesne, and Prévot 1932, Bengtson 1934, Hartley and White 1935, Walbum and Reymann 1935, Ssilanowa 1935, Weinberg and Guillaumie 1938, Ipsen 1939, Ramon 1940, Guillaumie 1941, 1942, 1943, Nagler 1941, Seal and Stewart 1941). The two chief methods used for titrating the antitoxin content are intramuscular or intravenous inoculation of mice, and intracutaneous inoculation of guinea-pigs or rabbits, with toxin-antitoxin mixtures. Other methods include flocculation tests analogous to the Ramon titration of diphtheria antitoxin, and, with *Cl. welchii*, neutralization of the lecithinase activity of the α-toxin. The *in vivo* titrations are at present the most reliable, and will probably remain so until the significance of the various toxic components in culture filtrates is fully understood. The international standards laid down by the League of Nations may be briefly defined.

as adjuvants to surgery, and in combination with antitoxin (see MacLennan 1943). Jeffrey and Thomson (1944) record a striking arrest of clostridial myositis by penicillin, but note that in some cases the arrest was followed by a fatal intoxication, apparently due to absorption of substances from the retained and degenerating muscle.

Active Immunization.—Formol and alum-precipitated toxoids induce in guinea-pigs and rabbits protective antitoxic immunity to experimental infection with *Cl. welchii*, *Cl. œdematiens* and *Cl. septicum* (Penfold and Tolhurst 1937, Penfold *et al.* 1941, Kesterman and Vogt 1940, Kolmer 1942, Stewart 1942, Robertson and Keppie 1943). As with other toxoids, a stimulating dose some time after the primary injections is necessary for high degrees of immunity. In man, the antitoxic response to these toxoids is good (Penfold and Tolhurst 1938, Stewart 1943*b*); but at present there are no data from which the value of prophylactic immunization can be estimated. It should be noted that in the guinea-pig, the response to a stimulating dose was not demonstrable for 3–10 days (Robertson and Keppie 1943). Immunization of man by means of a stimulating dose at the time of wounding is not, therefore, likely to affect the outcome of a disease of which the incubation period is commonly less than 2 days.

Other Clostridial Infections.—The active participation of toxigenic clostridia, especially of *Cl. welchii*, in the severe and sometimes fatal "toxæmia" that accompanies acute obstruction of the intestine or acute appendicitis has long been a matter of debate. Williams (1926) obtained evidence suggesting that the toxæmia was due to the formation of *Cl. welchii* toxin in the lumen of the obstructed small intestine, and that antitoxin was beneficial in the treatment of such cases. Paralytic ileus following acute inflammation in the abdominal cavity appeared to have the same effect as mechanical obstruction in the genesis of toxæmia; clostridial infection of the inflamed tissue was not observed. Weinberg (Weinberg *et al.* 1928*b*, Weinberg 1929), however, observed that clostridia could be obtained from 30 per cent. of acute lesions of the appendix (subsequent observers have recorded higher figures); and he tested the effect of antisera prepared against the gas-gangrene organisms in the treatment of conditions associated with an anaerobic invasion of the tissues (Weinberg and Howard 1927, Weinberg *et al.* 1928*a*). At most, it can be said that such antisera appear to reduce the case-fatality rates, especially when used in conjunction with surgical treatment (for later references see Priestly and McCormack 1936).

Bower, Burns and Mengle (1938) induced a fatal peritonitis in dogs by ligation of the appendiceal vessels, followed by a purgative dose of castor oil; *Cl. welchii* antitoxin reduced the mortality, and prolonged the lives of animals that eventually succumbed to the infection. Normal horse serum was also protective, but to a lesser extent—an effect attributed to the natural antitoxins in the serum. Prophylactic immunization with *Cl. welchii* toxin also reduced the death rate from this experimental disease (Mengle *et al.* 1938). The active participation of *Cl. welchii* may also be inferred from the fact that an antitoxin response is demonstrable in patients with appendicitis. Thus, Bower, Mengle and Paxson (1938) found that 22·2 per cent. of patients with acute appendicitis, 46·6 per cent. of those with active or quiescent pelvic peritonitis, and 69·0 per cent. of those with septic peritonitis after perforation, had more than 1 unit of *Cl. welchii* antitoxin per ml. of circulating blood. The corresponding figure in control patients was 0·0 per cent.

ANAEROBIC INFECTIONS OF ANIMALS

Blackleg and Gas Gangrene

SYNONYMS: Symptomatic anthrax, quarter-evil, blackquarter.
French: *Charbon symptomatique.* German: *Rauschbrand.*

Blackleg is a disease attacking cattle, sheep, and less often swine (Meyer 1915). It is characterized by the appearance of a crepitant, fluctuating swelling, generally on one of the quarters, followed rapidly by death. Calves are resistant for the first 6 months of life; they then become susceptible and remain so till about 2 years of age. The disease is commoner in the summer than in the winter. It may follow shearing, docking, parturition, or castration in sheep, but more often appears spontaneously. Arloing, Cornevin and Thomas (1881) first showed that the disease could be transmitted to cattle by inoculation of infective material. From the lesions, they isolated an anaerobic spore-bearing bacillus—*Cl. chauvœi.* The washed bacilli are non-infective, but they can be activated by a small dose of broth filtrate, or by substances such as lactic acid, potassium chloride, or sand (Nocard and Roux 1887, Roux 1888, Leclainche and Vallée 1900).

The term *gas gangrene* or *malignant œdema* is sometimes reserved for anaerobic infections of the muscle consequent on trauma. The essential pathology of blackleg and gas gangrene appears to be the same, and the distinction between the terms seems of doubtful value.

Blackleg in cattle seems to be generally caused by *Cl. chauvœi*, and in sheep by *Cl. septicum* (Heller 1920, Gaiger 1924, Weinberg and Mihailesco 1929), though *Cl. chauvœi* infections are not uncommonly found—especially if a bacteriological examination is made shortly after the death of the animal. Albiston (1937) records an outbreak of *Cl. chauvœi* blackleg in sheep, in which the local predisposing factor appeared to be a vaccine injected for immunization against enterotoxæmia (see below).

Vaccination has been practised for many years and has been attended by a considerable amount of success. Arloing, Cornevin and Thomas used two vaccines of different virulence; the first was prepared by exposing the dried juice from a blackleg tumour to 100–104° C. for 6 hours; the second by exposing it to 85–90° C. for the same time. Inoculation of cattle was practised subcutaneously on the under surface of the tail. Statistics compiled by Cornevin (1895) are given in Table 177.

TABLE 177

RESULTS OF VACCINATION AGAINST BLACKLEG IN CATTLE.

	No. of Animals Vaccinated.	Mortality due to vaccination.	
		Total.	Per 1,000.
1893	6,696	5	0·75
1894	8,222	8	0·97
1895 first 6 months . . .	6,936	5	0·72

The mortality in the vaccinated animals varied in different districts from 0–10 per 1,000; amongst the unvaccinated animals it varied from 20 to 250 per 1,000.

Several other vaccines have been employed (Roux 1888, Nitta 1919, Dalling 1925. See also *J. comp. Path.* 1895, **8**, 166). A formolized broth culture of *Cl. chauvœi* has been recommended (Leclainche and Vallée 1925, McEwen 1926); under experimental conditions, sheep injected with this vaccine appeared to derive a greater degree of immunity against subsequent inoculation with a living culture than sheep vaccinated with a non-formolized broth filtrate. Henderson's (1932) work suggests that the heat-stable O antigen is likely to prove a powerful immunizing agent. A high degree of protection against intramuscular injection of living cultures is produced in sheep by the subcutaneous inoculation of solutions of the heat-stable antigen (Mason 1936). Antitoxins are less effective against the bacterial invasion. However, sera for therapeutic use have been prepared against *Cl. chauvœi* and *Cl. septicum*, and their intravenous administration in cases of the fully developed disease appears at times to have given favourable results.

Braxy

SYNONYMS: *Bradsot* = quick plague.

Braxy is the term used for a disease of sheep occurring mainly in the north-western part of Europe. Recent work has rendered it clear that more than one type of disease is called by this name. For descriptive purposes we propose to reserve the term braxy for the type of disease characterized by inflammation of the fourth stomach, and to refer to the so-called German braxy by the term black disease or infectious necrotic hepatitis.

The classical or northern braxy occurs on the western coast of Norway, in Iceland, the Faroe islands, and Scotland. Sheep are most susceptible during their first year. The disease breaks out in the late autumn and early winter months when the animals descend from the hills to the pastures of the lowlands. In Scotland the losses from braxy in some districts may amount to as much as 35 per cent. of the first year's sheep (Gaiger 1924). Clinically, in the usual acute form of the disease, death occurs before any symptoms have been noticed; in the subacute form there is weakness, followed by coma, dyspnœa, and death. The duration of the disease is a matter of a few hours. Post mortem, there is severe inflammation of the fourth stomach and duodenum, with œdema and hæmorrhage—sometimes necrosis—of the mucosa and submucous tissue. The peritoneal fluid is often turbid and in excess; there are degenerative changes in the visceral organs, and an acute parenchymatous nephritis.

The causative organism was described by Nielsen in 1888, who found it in large numbers in the stomach wall. It was identified by Gaiger (1922) with *Cl. septicum*. The mode of infection is obscure; experimental feeding with pure cultures of the bacillus apparently fails to reproduce the disease; Jensen was successful only 5 times in 1,545 attempts (Gaiger 1924). Subcutaneous injection produces black-leg; post mortem, lesions may be present in the abomasum simulating those of the natural disease (Hamilton 1902, 1906); there is no evidence however that natural infection occurs by this route. Again we are forced to conclude that some accessory factor must be present before the bacillus is able to invade the tissues. Experimental work on guinea-pigs by Borthwick (1934) suggests that intestinal stasis and exposure of the animal to cold are important factors in determining the invasion of the tissues by *Cl. septicum*. While the feeding of cultures to normal guinea-pigs rarely set up infection, inhibition of peristalsis by narcotine, or pre-

liminary exposure to cold, resulted in the development of a fatal infection in a fairly high proportion of the animals.

A considerable degree of protection is afforded by the use of Jensen's sero-vaccine.

Gaiger (1922) obtained promising results by the use of a sterile filtrate of a culture of *Cl. septicum*. Of 10,340 hoggs (1st year sheep) vaccinated, 2·39 per cent. died of braxy, while among 3,800 control animals the mortality from braxy was 9 per cent. (see Gordon 1934*a*).

Dalling (1925, Dalling *et al.* 1925, 1926) advocated a combined vaccine against blackleg and braxy in sheep. He used a culture filtrate of *Cl. chauvœi* and a mixture of *Cl. septicum* toxin and antitoxin. During the winter of 1924, 549 sheep were inoculated, with a braxy mortality of 0·36 per cent.; of 464 unvaccinated sheep on the same farms and under the same conditions 15·5 per cent. died of braxy. Satisfactory results were also obtained by Gordon (1934*a*) using a formolized whole culture of *Cl. septicum*. Preliminary experiments on sheep showed this to be superior to Gaiger's filtrate vaccine, and it was therefore used for further trial. Of 3,588 vaccinated hoggs, 73 (0·8 per cent.) died of braxy, while of 1,886 control animals on the same farms, 158 (8·4 per cent.) died of this disease. The vaccine is prepared by adding 0·5 per cent. formol to a 15-hour horse flesh broth culture and incubating at 37° C. for 2 days. By this time it should be bacteriologically sterile, and should prove non-toxic when inoculated intravenously into mice in a dose of 0·5 ml. Dungal (1932) in Iceland also reported favourable results from the use of a formolized whole culture vaccine of *Cl. septicum*. Comparison with Jensen's sero-vaccine yielded the following figures. Of 11,308 sheep given the sero-vaccine, the mortality from all causes was 2·44 per cent. whereas of 59,736 sheep given the formolized vaccine, it was only 0·84 per cent.

Black Disease

SYNONYMS: Infectious necrotic hepatitis; German braxy.

This disease occurs in Australia, particularly Victoria, New South Wales, and Tasmania, and in certain parts of Germany, where it is termed braxy. In Germany two types are recognized: (1) Meadow braxy, affecting mainly ewes at pasture in well-watered valleys; and (2) Stall braxy, affecting chiefly young castrated lambs that are being fattened for market (Miessner, Meyn, and Schoop 1931). In Australia the meadow type alone seems to be common. Well-nourished animals are affected. Clinically the course in meadow braxy is usually very acute, and the animals are often found dead before suspicion of illness has been aroused, but in stall braxy symptoms may be present for 12 hours before death. Examination of fresh carcasses reveals the presence of subcutaneous venous engorgement, which gives the skin a dark colour—hence the term black disease—amber-coloured fluid in the pericardial and peritoneal cavities, and characteristic necrotic areas in the liver. Unlike true braxy the abomasum is slightly or not at all affected, and no obvious degenerative changes are present in the visceral organs. The liver lesions are most typical of the disease. Greenish bile-stained areas of necrosis, about 1 cm. in diameter, containing cavities filled with blood clot and immature liver flukes, are usually seen in small numbers. In addition to these non-specific foci, there are a few characteristic, irregularly circular, necrotic areas, 2–3 cm. in dia-

meter, sharply defined, yellowish-white in colour, and surrounded by a wide zone of venous congestion. Bacteriologically the liver can be shown to contain large anaerobic bacilli, which are refered to by the Germans as *Cl. gigas*, but which appear to be identical with, or a variety of, *Cl. œdematiens*.

The pathogenesis of the disease has been elucidated by Dodd (1918, 1921), Albiston (1927), and particularly Turner (1930), who sought for predisposing factors which, as Fildes had demonstrated in the case of infections with *Cl. tetani* (Chapter 77), would increase the reducing intensity of the tissues so as to favour the germination of the spores of *Cl. œdematiens*. By a careful series of observations and experiments, Turner was able to show that in black disease the necessary conditions for growth of the causative organism were found in the necrotic areas produced by invasion of the liver with wandering immature liver flukes of the species *Fasciola hepatica*. In these areas the organisms multiplied, and gave rise to a toxin which was responsible for the main features of the disease. Many sheep were found to be latently infected with the spores of *Cl. œdematiens*, but not until suitable necrotic foci were established by invasion with liver flukes did the infection become active.

Consequent on this work Turner prepared a formolized broth vaccine with which very satisfactory results were obtained in field trials. The figures showed that when two doses were given, the mortality from black disease was reduced on an average by about half, as compared with control animals on the same farm. Even more favourable results attended the use of three doses of vaccine.

Vaccination of over 270,000 sheep in Victoria, Australia, during the years 1933–36 was accompanied by a reduction in the annual mortality due to black disease from 4–15 per cent. to 0·02–0·05 per cent. (Wardle 1936; see also Rose 1936). According to Oxer (1937) alum-precipitated vaccine is a more efficient immunizing antigen.

Osteomyelitis of Buffaloes.—The buffaloes of the Dutch East Indies suffer from a non-fatal osteomyelitis, which particularly affects the humerus and femur. The causative organism is indistinguishable from *Cl. gigas*, except that it is non-pathogenic to laboratory animals. The pathogenesis of the disease is obscure; and inoculation of the buffalo with the organism is not followed by osteomyelitis (Kraneveld 1930, Kraneveld and Djaenoedin 1933).

Infections due to Cl. welchii : Lamb dysentery ; "Struck" ; infectious enterotoxæmia ; pulpy kidney disease

A number of acute toxæmic diseases have been described in different parts of the world, mostly affecting sheep, in which the lesions appear to result from an intestinal infection with a variety of *Cl. welchii*. The pathogenesis of these diseases is to a large extent obscure, but considerable progress has been made in their control by vaccination and serotherapy.

Lamb dysentery is a disease that takes a heavy toll of life among the lambs during their first 2 weeks of life (Gaiger and Dalling 1921). It is particularly prevalent in the border counties of England and Scotland. Pathologically it is characterized by an enteritis varying from a mild congestion of the intestinal mucosa to a condition in which extensive tracts of the small and large intestine become necrosed and ulcerated. On the surface of the inflamed mucosa and ulcerated areas a bacillus is found closely allied to *Cl. welchii*, but differing from it in certain cultural particulars and in its production of a more powerful toxin (Dalling *et al.*

1925, Dalling 1928*b*, 1931–32). This organism is sometimes referred to as the lamb dysentery bacillus, and sometimes as the *agni* variety of *Cl. welchii*. It is at present probably better to call it *Cl. welchii* Type B (see Chapter 36). The organisms are confined mainly to the intestine, and the body tissues are not usually invaded. Dysentery associated with *Cl. welchii* Type B has also been reported in foals (Mason and Robinson 1938).

Protection against the disease can be afforded in one of two ways: (1) the pregnant ewe may be immunized with an over-neutralized toxin-antitoxin mixture, or with a simple formolized culture. Both of these methods of inoculation appear to give satisfactory results. Thus in one field experiment, the mortality from lamb dysentery amongst 741 lambs born of ewes inoculated with the toxin-antitoxin mixture was 1·07 per cent.; amongst 1,157 lambs born of ewes inoculated with a formolized culture it was 1·12 per cent.; while amongst 2,530 control lambs born of uninoculated ewes on the same farms it was 13·09 per cent. (Dalling 1928*b*. For further records see Dalling 1926, Dalling, Mason, and Gordon 1928, 1929). The antibodies generated in the ewe by this method are transferred to the new-born lamb by means of the colostrum (Dalling 1928*a*, Mason, Dalling, and Gordon 1930). (2) The new-born lamb may be injected directly with antitoxin. This method likewise gives satisfactory results. Thus on 15 farms in 1927 the mortality from lamb dysentery amongst 1,122 lambs injected with serum was 0·44 per cent., while amongst 1,241 control lambs on the same farms it was 17·16 per cent. (Dalling 1928*b*).

"Struck" is the local name given to a disease of sheep occurring during the late winter and spring months on the Romney Marsh in Kent. Clinically the symptoms are of short duration, and the case mortality is high. In fresh carcasses the main lesions are those of an acute enteritis and peritonitis, but in animals that have been dead for some hours the subcutaneous and muscular tissues present a picture similar to that found in gas gangrene. The work of McEwen (1930) and McEwen and Roberts (1931) seems to show that the disease is essentially a toxæmia consequent on the multiplication in the intestinal canal, and perhaps the body tissues, of an organism resembling *Cl. welchii*. The name *Cl. paludis* has been suggested for it, but until we know more of the relationship between this organism and other closely allied members of the *welchii* type it is probably better to refer to it as *Cl. welchii* Type C. Vaccination with toxoid is apparently of value in protecting against the disease (McEwen 1935).

Infectious enterotoxæmia is a disease of sheep described by Bennetts (1932) in Western Australia, and apparently due to the absorption of toxin from the small intestine. The organism, for which the name *Cl. ovitoxicum* has been suggested, appears to be more or less identical with Wilsdon's (1931, 1933) *Cl. welchii* Type D, and is better referred to by this name. The same organism appears to be responsible for the condition known as **pulpy kidney disease of lambs,** which has been studied in New Zealand by Gill (1932) and in Wales by Montgomerie and Dalling (1933) and Montgomerie and Rowlands (1933, 1934). Immunization of sheep with a formol-treated culture, which presumably contains both bacterial and exotoxin antigens, appears to lower the incidence of infectious enterotoxæmia (Bennetts 1936, Rose 1936). Death from pulpy kidney is commonest in 3–6-week-old lambs, so that active immunization of the new-born lamb is unlikely to be successful. Protection is achieved by the vaccination of the pregnant ewe, the lambs rapidly acquiring a passive immunity by ingestion of the maternal antitoxin

present in the colostrum (Oxer 1936, Dayus 1938). Gordon (1934*b*), who examined filtrates of intestinal contents from lambs, sheep, and horses that had apparently died of acute toxæmia, was able to demonstrate the presence of a toxin neutralizable by an antitoxin to *Cl. welchii* Type D. His work suggests that this organism may play a part in a number of diseases of sheep, lambs, and perhaps horses.

The conditions governing the formation of a toxin in most of the diseases that we have been discussing are still obscure, and there is a considerable field open for an investigation of the type so successfully undertaken by Turner (1930) in black disease. It is interesting to reflect that whereas anaerobic infections in man and the carnivora are generally preceded by trauma, in herbivora they often occur spontaneously (Heller 1920).

The genesis of enterotoxæmia affords an illustration of the complexity of the problem. The main clinical and pathological findings in this disease appear to be the result of intoxication by the ε-toxin (Nicholson 1934–35, Kellaway, Trethewie and Turner 1940, Gordon *et al.* 1940). In 1935 Bosworth and Glover observed that the lethal power of the toxin of *Cl. welchii* Type D, but not of Types A, B or C, was increased when added to an intestinal filtrate of a normal sheep, guinea-pig or rabbit. But in spite of the increase, exactly the same amount of antitoxin was required to neutralize the toxin, whether it was free or mixed with the intestinal filtrate. These workers suggested that the toxin might form a highly toxic complex with the intestinal tryptic ferments, possessing some of the properties of histamine. More recently Turner and Rodwell (1943) have reported that all kinds of proteolytic enzymes, including those of *Cl. welchii* itself, can "activate" the ε-toxin; they postulate an ε-prototoxin which may be converted by any of these enzymes into ε-toxin. As regards the conditions for toxin formation in the gut, Roberts (1938) concluded from *in vitro* and *in vivo* experiments that in milk-fed lambs, the acidity of the abomasum contents normally prevented any proliferation of *Cl. welchii*. If infective material is present after the ingestion of an abnormally large feed, the acidity is depressed by the casein in the feed, and *Cl. welchii* Type D may proliferate, producing a toxin which is activated in the small intestine.

The source of infection is presumably *Cl. welchii* Type D in the soil, though it is found there only occasionally, Type A or non-toxic *Cl. welchii* being the predominating varieties (see Taylor and Gordon 1940). However, it is known that Type D strains readily lose their power to produce ε-toxin on subculture (Borthwick 1937), and it is possible that many of the Type A strains found in soils and the intestinal content of animals may be degraded Type D strains.

(For an account of the anaerobic toxæmias of animals, see Woodruff 1936.)

For **botulism** in animals see Chapter 72.

CHAPTER 79

MISCELLANEOUS DISEASES

NECROBACILLOSIS, OZÆNA, RHINOSCLEROMA, GRANULOMA VENEREUM, SOFT CHANCRE, GLANDULAR FEVER, INFECTIVE HEPATITIS, BARTONELLA INFECTIONS, AND VARIOUS OTHER DISEASES

NECROBACILLOSIS

THIS term may be used to cover a wide variety of lesions in man and animals due to infection with the non-sporing anaerobic bacillus known as *Fusiformis necrophorus* (see Chapter 18).

In *man*, infections by organisms of the *F. necrophorus* group, which includes those strains named *B. funduliformis*, seem to be rare. This may result from failure to submit all material from purulent infections to routine anaerobic cultivation. Holicky (1940), for example, records that Gram-negative, anaerobic non-sporing rods and fusiform bacilli were obtained, sometimes in pure culture, from about 2 per cent. of over 5,000 specimens from infected patients in a surgical clinic. Judging from the species-frequency observed in human infections, it is probable that the majority of the strains isolated were of *F. necrophorus* type.

The disease may take the form of purulent or gangrenous inflammation of the skin (see Shaw 1933). The mode of infection is not always clear, but a number of cases have followed bites or injuries from the teeth of animals. More commonly it occurs as a deep-seated infection, with purulent abscesses in the abdominal cavity, liver or lung, many of which appear to be the result of a pyæmia. It often complicates operations on appendix abscesses or other septic lesions of the lower gut. The case mortality among patients with well-established infection is over 50 per cent. The infecting organism is presumably derived from the alimentary tract, though *F. necrophorus* has seldom been isolated from normal stools. In some instances, however, *Fusiformis* strains from infective lesions in man resemble those found in normal tissues. Thus, Spaulding and Rettger (1937) demonstrated cultural and serological similarities between strains from the normal and from the infected mouth and vagina, and from lung abscesses. What relation the disease has to Vincent's angina (see Chapter 80), and to the various necrotic stomatitis conditions in which the closely related organism *Fusiformis fusiformis* seems to play a part, is not clear.

It is impracticable to review the types of human infection that have been reported, but we may note the following. Puerperal sepsis (Harris and Brown 1927, Delbove and Reynes 1941); abdominal, hepatic or lung abscesses (Cunningham 1930, Cohen 1932, Thompson and Beaver 1931, Shaw and Bigger 1934, Beaver, Henthorne and Macy 1934, Henthorne, Thompson and Beaver 1936, Lemierre 1936, Dixon and Deuterman 1937,

Brunner 1937, Buhler, Seely and Dixon 1942); Chandler and Breaks (1941) record a case of femoral osteomyelitis, Forbes and Goligher (1944) a generalized pyæmia following a war-wound infection.

Among other fusiform bacilli *F. fragilis* produces infections in man similar to those of *F. necrophorus* (Thompson and Beaver 1931, Henthorne, Thompson and Beaver 1936). *F. ramosus* (Lemierre, Reilly and Bloch-Michel 1937) and *F. melaninogenicus* (Oliver and Wherry 1921, Burdon 1928, Weiss 1943) are associated with less severe infections, apparently originating, like *F. necrophorus* infections, from the respiratory or genital tract; and though they are sometimes found in the blood stream their power to initiate infection in healthy tissue appears to be limited.

Dack and his colleagues have studied the relation of *F. necrophorus* to ulcerative colitis. They find that the flora of the ulcerated colon differs from that of the normal colon in consisting of anaerobic organisms, with *F. necrophorus* predominating during periods of exacerbation of the disease, and disappearing during periods of quiescence. The organism is not found in the normal colon. Its causal rôle in the disease is not clear, but material from human lesions is said to induce necrotic lesions in the colon of monkeys. Moreover, agglutinins for *F. necrophorus* are present in the serum of patients with ulcerative colitis, but not in sera from normal persons (Dack, Heinz and Dragstedt 1935, Dack, Dragstedt and Heinz 1936, 1937, Dack *et al.* 1938, Dack *et al.* 1939*a*). These facts, as Dack points out, do not establish *F. necrophorus* as the cause of ulcerative colitis, but indicate that it at least plays a part as a secondary invader of the lesions. It is noteworthy that sulphanilamide has been found to have a beneficial effect in experimental lesions produced by *F. necrophorus* in rabbits (Hemmens and Dack 1939), but not to affect the course of ulcerative colitis in man (Dack *et al.* 1939*b*).

In *animals*, necrobacillosis takes the form of calf diphtheria, necrotic stomatitis of cattle, foot-rot of sheep, gangrenous dermatitis of horses and mules, hepatic necrosis of cattle, pigs, and sheep, labial necrosis of rabbits, and a number of other conditions (see Beveridge 1934).

In **calf diphtheria,** which was studied by Loeffler (1884), a false membrane stretches from the throat down into the trachea; the superficial parts are caseous and friable, the deeper parts firmly adherent. Microscopically the membrane consists of a superficial layer containing large numbers of micrococci: a middle layer, amorphous and unstained; and a deep layer containing granular detritus with some cells and the characteristic long wavy rows of bacilli; these are separated by a narrow unstained zone from a dense infiltration of cells. The lungs contain pneumonic foci, in which much the same microscopical picture is evident. A similar disease to calf diphtheria is said to occur in lambs.

Foot-rot of sheep is usually regarded as due to *Fusiformis necrophorus*, but Beveridge (1935, 1938) in Australia has cast doubt on this. He finds that neither *Fusiformis necrophorus* nor *Treponema penorthum*, which can be seen microscopically in smears from the lesions, are able, alone or together, to set up the disease in healthy sheep. On the other hand, a long, anaerobic, Gram-negative, non-sporing rod having knob-like ends, which was present in smears in only small numbers, was cultivated in a medium containing 25 per cent. of serum, and when applied in pure culture, or better still with *Trep. penorthum*, gave rise to typical foot-rot in healthy adult Merino sheep. Beveridge, who refers to this organism as " organism K," thinks that it belongs to the *Bacteroides* group, but from the description he gives it seems more probable that it is a species of *Fusiformis*. Working with scrapings from lesions, not with pure cultures, Beveridge found that the infecting agent, as judged by its ability to cause foot-rot in healthy sheep when applied to the

scarified area between the digits, might survive for a few days in mud or in sheep fæces, but never for as long as 3 weeks. On the other hand, it could persist for over 3 years in lesions of chronically infected sheep, and for as long as 7 months in superficial skin lesions between the digits. Sheep, however, that had recovered from the disease for a month or more appeared to be no longer infective. Since the causal agent does not survive for more than a short time under saprophytic conditions, it should be possible to free pastures from infection by removal, preferably during the summer, of all infected sheep.

Labial necrosis of rabbits is characterized by a dark bluish-red discoloration of the under lip, accompanied by a tender swelling. The infiltration passes gradually down the under surface of the mouth and front of the neck, and in about 8 days reaches the upper opening of the thorax. Constitutional symptoms develop about the 5th day; a thin watery discharge comes from the nose; the respirations increase in rate; the temperature rises 1–1·5° C. and the animals die in an emaciated condition with marked dyspnœa. Post mortem, section shows that the under lip is converted into a yellowish-white, compact, bacon-like, necrotic mass, which in places extends to the bone; around the necrotic mass is a reddish-black border. The cervical glands are greatly swollen, juicy, and greyish-red; sometimes they show small caseous foci. There is bloody, slightly turbid fluid in the pleural and pericardial cavities with some fibrin deposit on the surrounding serous membranes. A few pneumonic areas may be seen in the lungs, with yellowish-white streaks passing from the pleura into the dark red pulmonary tissue. The spleen and other viscera appear normal. The disease was first described by Schmorl (1891), who observed an epidemic among his laboratory rabbits.

The diagnosis of necrobacillosis is made by morphological and cultural methods. In the lesions the organisms appear mostly as Gram-negative wavy non-branching filaments lying parallel to one another. Attempts to isolate them may be made directly by the inoculation of serum agar shake cultures, or by streaking plates of blood or potato extract agar containing 1/10,000–1/20,000 gentian violet and incubating anaerobically (Slanetz and Rettger 1933). In view of the extreme oxygen sensitivity reported in some species of *Fusiformis*, surface plates should be subcultured as soon as possible after removal from the anaerobic atmosphere. The incorporation in the plate media of reducing substances like thioglycollic acid, which prolongs the life of colonies of oxygen-sensitive clostridia when exposed to air (N. J. Hayward pers. comm.), may prove to be similarly effective with colonies of *Fusiformis*. As an alternative method of diagnosis, a tissue suspension may be inoculated subcutaneously into rabbits, and cultures made from the blood a few hours before death (Scrivner and Lee 1934). The agglutination reaction does not provide a reliable index of infection in animals. Apart from fallacies due to the instability of suspensions of some strains of *Fusiformis* bacilli, titres of up to 1 : 800 are found in the blood of normal adult horses, cattle, sheep and swine (Feldman, Hester and Wherry 1936).

OZÆNA

Ozæna is a disease characterized by atrophy of the nasal mucosa, and the secretion of muco-pus, which dries into greenish-yellow crusts with a peculiarly foul and penetrating odour. It starts generally in childhood or adolescence, and persists throughout life. Though a great many workers have studied the disease, its ætiology still remains doubtful; indeed, it is not clear whether it is an infective disease at all. For a long time there were, among those who supported the in-

fective theory, two rival schools: one, following Loewenberg (1894) and Abel (1896), maintained that the disease was caused by the *B. mucosus ozænæ*—a member of the group of Gram-negative capsulated bacilli (see Chapter 28); the other maintained that the primary cause was Perez's bacillus (Perez 1899, 1901, 1913) (see Chapter 19). A fact in favour of the former group was the isolation of the Loewenberg-Abel bacillus from nearly every case of the disease; in favour of the latter group was the reproduction of a chronic rhinitis by intravenous injection of Perez's bacillus into rabbits.

We do not propose to discuss the evidence for and against the claims of these rival schools; it is sufficient to point out that most of the early workers entirely underestimated the difficulty of establishing the ætiological rôle of any organism isolated from such a situation as the nose. And since diseases such as ozæna and rhinoscleroma have not yet been reproduced with certainty in animals, it is impossible to make out a strong enough case in favour of any one organism to warrant belief in its specific ætiological rôle.

At the present day few workers would care to dogmatize about the causation of ozæna. The general trend of opinion is that the organisms described by Loewenberg, Perez, and others are merely secondary invaders, which are able to multiply abundantly in the altered conditions accompanying an atrophic rhinitis. (For further references see Fricke 1896, Page 1912, Hofer 1913*a*, *b*, Ward 1916, 1917, Shiga 1922, Busson 1923, Blanc and Pangalos 1925, Olinescu and Atineu 1925.)

RHINOSCLEROMA

Rhinoscleroma is a disease of the nose and upper part of the respiratory tract, characterized by proliferative lesions of the infective granuloma type. It is confined to man, and occurs endemically in Eastern Europe and sporadically elsewhere. Most of the reported cases have occurred in Slavs. It would appear to be either non-contagious or only slightly contagious (Perkins 1907). It has not been transmitted to animals.

Bacteriologically rhinoscleroma stands in much the same position as ozæna. In 1882 von Frisch cultivated a member of the group of capsulated bacilli from the lesions; he called it *B. rhinoscleromatis*. By injecting cultures into the submucous tissue of the nasal septum, he produced in rats a small tumour, which contained the organisms (Galli-Valerio 1911). Though Frisch and his followers regarded the disease as caused by this bacillus, there is very little evidence to show that this organism is primarily responsible for it. There is no means by which it can be distinguished with certainty from other members of the capsulated group; and since we know that members of this group may be present in the nose of healthy persons, it is difficult to prove that they play any part in the production of rhinoscleroma. The probability is that they are mere secondary invaders, which grow freely in the nose of patients suffering from the disease.

Tomášek (1925), Quast (1926), and Kouwenaar, Maasland, and Wolff (1934) state that the majority of cases give a positive complement-fixation reaction with a suitable antigen prepared from the rhinoscleroma bacillus, whereas control cases of ozæna and other respiratory diseases fail to do so. The test appears to be of some value in epidemiological survey work.

GRANULOMA VENEREUM

SYNONYM: *Granuloma inguinale*

This disease, which is not to be confused with lymphogranuloma inguinale (see p. 1869), is a venereal disease characterized by a slowly progressive ulceration of the tissues in the genital region. It is widespread in the tropics. Both sexes are attacked. The incubation period varies from a few days to 2 or 3 months. Spontaneous cure is uncommon, but the infection is susceptible to treatment with antimony.

Many years ago Donovan (1905) described the constant presence in smears from the ulcerated lesions of characteristic intracellular bodies, which he regarded as parasites, and which now usually bear his name. They are often contained in giant mononuclear cells. They resemble bacilli of the Friedländer group, are Gram-negative and are surrounded by a well-defined capsule, which can be demonstrated by Wright's stain. Non-capsulated forms, however, are also present. In spite of several claims to have cultivated the causative organism, the precise agent responsible for this disease remained obscure till Anderson, DeMonbreun and Goodpasture (1945) succeeded in cultivating it in the yolk sac of the developing chick embryo. The organism will not grow on ordinary media nor on the chorio-allantoic membrane. It requires some substance present in the yolk of a fertile egg for its nutrition. After a little adaptation it will grow in yolk removed from the embryo and transferred to a test-tube. Yolk from embryos in the early stages of development (4–8 days) is better than that taken later (12–14 days). The growth-supporting substance in yolk withstands heating at 60° C. for 30 minutes. In cultures the organism is moderately pleomorphic, capsulated and uncapsulated forms, long bipolar-stained bacilli, safety-pin forms, and short chains of irregularly stained rods being met with. In sealed test-tubes, cultures may remain viable for 4 or 5 weeks at 25° C. Injection of cultures into a variety of animals, including monkeys, fails to set up progressive disease. Anderson and her colleagues therefore conclude that the causative organism of granuloma venereum is a specific human bacterial parasite having—so far as is known at present—unique growth requirements, and they suggest for it the name *Donovania granulomatis*.

In a further paper, Anderson, Goodpasture and DeMonbreun (1945) describe the preparation from chick embryo yolk cultures of a washed bacterial suspension which gives rise, on intradermal injection into patients suffering from the disease, to a red œdematous reaction reaching its height in 24 hours and disappearing within another 2 days. They were also able to extract with weak alkali a mucoid material, probably of capsular origin, which gave specific precipitin and complement-fixation reactions with the sera of granuloma patients. These results leave little doubt that the true causative organism of this disease has been discovered, and they open the way to a biochemical study of the essential food requirements of this interesting bacterial parasite.

SOFT CHANCRE OR ULCUS MOLLE

Soft chancre is a non-syphilitic lesion of the external genitals and neighbouring regions due to infection with *Haemophilus ducreyi*, a small Gram-negative bacillus first described by Ducrey (1889), and generally known by his name. For

the differential diagnosis of this disease from syphilis by clinical methods, textbooks on venereal diseases must be consulted.

There appears to be little doubt that Ducrey's bacillus is responsible for soft chancre, and for the buboes which are sometimes associated with the primary lesion. Tomasczewski (1903) was successful in reproducing the disease in human subjects with pure cultures. Ulcerative lesions have likewise followed the inoculation of monkeys and rabbits with cultures several generations removed from primary isolation (Reenstierna 1921, Nicolle, 1923). In the diagnosis of the disease, microscopical and cultural examinations should be made in the way already indicated in Chapter 33. An intradermal reaction has been described, and is said to give a high percentage of positive results in infected subjects (Reenstierna 1923, Cole and Levin 1935). The growth from a blood-agar culture is washed off in 0·5 per cent. phenolized saline, and kept in the ice-chest till it is completely sterile. For the test, 0·2 ml. of the suspension is inoculated into the skin. A positive reaction is characterized by the development of a large circular papule with an inflamed border, reaching its maximum in about 48 hours. Care, however, is required in the interpretation of the reaction, since patients who are suffering from lymphogranuloma inguinale may react to the Ducrey antigen, and patients who are suffering from chancroid may react to the Frei test for lymphogranuloma inguinale. A positive reaction, therefore, to one of these tests only is of more diagnostic value than a reaction to both (Greenblatt and Sanderson 1937, Dulaney, 1937).

Vaccine treatment, and treatment with an antiserum prepared by the inoculation of rams, have been stated to yield satisfactory results (Reenstierna 1923, Nicolle and Durand 1924, Hababou-Sala 1925, Watanabe 1939).

GLANDULAR FEVER

SYNONYM: *Infectious Mononucleosis*

Glandular fever is a disease of human beings that was first described by Pfeiffer in 1889. Türk (1907) recognized the peculiar lymphoid blood picture, and Sprunt and Evans (1920) suggested the alternative name of infectious mononucleosis. It is an acute infectious disease characterized by fever, enlargement of the lymphatic nodes and spleen, angina, and changes in the lymphocytic cells of the blood. Acute abdominal symptoms, follicular conjunctivitis, jaundice, and a rash, usually of the rubella type, are sometimes observed. The duration of the disease is variable. Relapses are not infrequent; but fatal cases are rare. No fewer than five different clinical types of the disease have been described by Baldridge, Rohner and Hansmann (1926). Tidy (1934) divides it into three clinical types according to whether the glandular enlargement, the sore throat, or the fever predominates. Abortive and ambulant cases are very common. Children and young adults are mainly attacked. The incubation period is about 7 to 12 days, but may be as long as 21 days. The disease is contagious and may occur in epidemic form (see Tidy and Morley 1921, Tidy and Daniel 1923); but the infectivity of sporadic cases is said to be low (Glanzmann 1930).

The *cause* of the disease is still open to doubt. Schmidt and Nyfeldt (1938) described five cases of infectious mononucleosis accompanied by meningo-encephalitis, and found *Erysipelothrix monocytogenes* (*Listerella*) in the blood or cerebrospinal fluid of four of them. Pons and Julianelle (1939) also isolated the same organism

from the blood of a patient, and Webb (1943) records a similar finding. With few exceptions, however, subsequent workers have failed to confirm these observations. Wising (1942), in particular, made a very careful study of 27 typical cases of the disease, but neither from the blood in the acute febrile stage nor from excised lymph nodes was he able to cultivate this organism. Convalescents from glandular fever contained no agglutinins in their blood to *Ery. monocytogenes*. Inoculation of killed *Ery. monocytogenes* into human volunteers did not give rise to a Paul-Bunnell reaction (see below); and inoculation of the living organisms into monkeys led to a rapidly fatal septic infection accompanied by suppurative meningitis and encephalitis, which was unlike typical glandular fever in man.

On the other hand, evidence is accumulating to suggest that the disease is caused by a filtrable virus having a predilection for lymphatic tissue. Van den Berghe and Liessens (1939*a*, *b*) and van den Berghe, Liessens and Kovacs (1939) were able to produce a circulating monocytosis in a monkey by intramuscular inoculation of 4 ml. of oxalated blood from a child suffering from glandular fever, and to reproduce a similar result in a second monkey inoculated with blood from the first monkey after it had been hæmolysed and filtered through a Seitz EK disc. The virus was grown in tissue culture, and still proved capable after ten generations of causing a monocytosis in monkeys. Mice inoculated intracerebrally proved insusceptible. Nettleship (1942) described the production of pearl-grey nodules with heavy monocytic cell infiltration in the chorio-allantoic membrane of chick embryos inoculated with Berkefeld filtrates of nasal washings or with whole blood of glandular fever patients. Wising (1942) failed to reproduce the disease in rabbits inoculated intravenously with heparinized blood of febrile patients, but had some success with monkeys. Of seven *Macacus* or *Cercopithecus* monkeys inoculated intracerebrally, intraperitoneally, or subcutaneously with fresh lymph node suspensions from patients in the acute stage of the disease, three developed mild clinical symptoms with general enlargement of the lymph nodes, coming on after 8, 17 and 19 days respectively. There was also a slight monocytosis. These changes were reproduced in fresh monkeys by inoculation of excised lymph nodes; 2, 3 and 5 passages were made successfully with the three different strains. Histological examination of the nodes revealed the typical irregular pleomorphic and large-celled hyperplasia seen in man. Of six human volunteers inoculated with heparinized blood or plasma from patients in the acute stage, five remained well. The sixth, who had received 250 ml. of blood, developed typical glandular fever 18 days later.

These results are by no means conclusive. It may be that, as Schultz (1930) and Höring (1933) think, glandular fever is a name covering two or three different diseases. One of these, probably the commonest type, may be caused by a virus; another, probably much less common, may follow infection with *Erysipelothrix monocytogenes*. Further investigations, however, are required to establish this thesis.

Laboratory diagnosis is made by cytological examination of the blood and by the Paul-Bunnell test. Though there is usually a relative lymphocytosis, it is not the absolute nor the relative numbers of the lymphocytes that is characteristic so much as the special morphology of the cells. Blood changes may be present even on the first day of fever, but they do not usually reach their maximum till the end of the second week. They persist for weeks or months. The ability of the blood of glandular fever patients to agglutinate sheep red corpuscles was

described by Paul and Bunnell (1932). Normal agglutinins, rarely exceeding a titre of 1/56, may be found in healthy persons (see Smeall 1942), and the heterophile antibody content may rise after injection of horse serum. Observations by Stuart and his colleagues (1934), Bailey and Raffel (1935), Davidsohn (1937), Kristensen (1938), Barrett (1941), and Kilham and Steigman (1942) have shown that the normal heterophile antibody can be absorbed completely from the serum by guinea-pig kidney, that that met with in serum disease can be absorbed by guinea-pig kidney and ox red blood corpuscles, and that the heterophile antibody of glandular fever can be absorbed by ox corpuscles but not by guinea-pig kidney. The Paul-Bunnell test, particularly when confirmed by absorption, is of considerable value in diagnosis. A titre of 1/80 or over is highly suggestive of infection, though some workers, such as Halcrow, Owen and Rodger (1943), would put it as low as 1/32. The agglutinin content often continues to rise for 2 or 3 weeks. Not all cases, however, give a positive reaction. Shafar and Weir (1943), for example, have described an outbreak of glandular fever in Scotland affecting about 200 persons, in which the Paul-Bunnell reaction was almost uniformly negative. McFarlan and Macfarlane (1943) likewise have described an outbreak in a girls' school affecting 78 of the pupils, in which typical blood changes were present but in which not a single serum reacted positively in the Paul-Bunnell test. The explanation of this is doubtful. It may be that there is more than one type of the disease, or that in some cases the amount of virus in the circulating blood is too small to react in the presence of sheep red corpuscles; or that only the first stage of the antigen-antibody reaction occurs (see Levine and Gilmore 1945). The mechanism of the reaction is likewise still doubtful, but it may be similar to that of the Hirst test in influenza (see p. 1658); if so, then the antibody titre may be an index of the amount of circulating virus.

Treatment of the disease by the sulphonamides has not so far proved encouraging. (For references to papers and reviews on glandular fever see Tidy and Morley 1921, Baldridge *et al.* 1926, Schwarz 1929, Glanzmann 1930, Tidy 1934, Anton 1934, McKinlay 1935, Wising 1942, Halcrow *et al.* 1943.)

INFECTIVE HEPATITIS

SYNONYMS.—Epidemic jaundice; common infective jaundice.

Infective hepatitis is a disease that tends to occur in epidemics. Clinically it is characterized by a sudden onset with vomiting, fever, malaise, and sometimes abdominal pain. Jaundice develops in a few days, being apparent first in the conjunctiva, and then spreading to the rest of the body; frequently it gives rise to itching. The urine is dark and the stools are pale. Bradycardia is common and the liver is often enlarged and tender. The disease lasts from a few days to three weeks or more, but complete recovery may take some months. Relapses may occur, but are not common. The morbidity varies greatly. The disease may be confined to sporadic cases, or it may affect up to 50 per cent. of the exposed population. Abortive and ambulant cases are not uncommon, and there is evidence that healthy carriers may occur. The sexes appear to be equally susceptible. The disease is most frequent in children of school age, but young adults are also affected. The incubation period is generally 3 to 5 weeks, though Sheehan (1944) maintains that it is probably 3 months. The period of infectivity appears to be

confined to the first week or two at most of the disease. Multiple cases in a household, sometimes occurring at approximately 4-week intervals, are often observed. As a rule, the case mortality is not more than about 0·1 per cent., but in some localized outbreaks quite a number of the patients may die. The histological appearance of the liver at autopsy, or as revealed by biopsy (Roholm and Iversen 1939), is one of diffuse lobular necrosis with mononuclear infiltration and a varying degree of connective tissue proliferation, but without involvement of the bile ducts.

The disease is supposed to be conveyed by droplet infection, but one water-borne outbreak has been described by Fraser (1931) in Canada, and one milk-borne outbreak in Scotland, affecting about 150 school children (Report 1943*b*). Andersen (1937) and Andersen and Tulinius (1938) in Denmark thought that infection occurred usually by the alimentary tract, and that the disease was ætiologically related to epidemic jaundice in pigs. The observations, however, on which these workers based their conclusions have not been confirmed. Sheehan (1944) quotes evidence suggesting that the disease is borne by insects—possibly bed bugs. On the whole the evidence suggests that infection is usually conveyed by droplet nuclei from the nasopharynx or by infected dust, which are inhaled or come into close contact with the retropharyngeal tissues during ingestion. The ætiology of the disease is still obscure. So far, no micro-organisms have been identified as a likely cause. Mention, however, should be made of the water-borne outbreak of jaundice described by Fraser (1931), in which jaundice followed 3–5 weeks after an outbreak of acute gastro-enteritis caused apparently by *Salm. paratyphi B* or some closely related organism of the *Salmonella* group. German workers (Siede and Meding 1941, Mancke and Siede 1942, and Siede and Luz 1943) claim to have cultivated a virus from the duodenal juice of patients on the chorio-allantoic membrane of the developing chick embryo, but attempts by Hoyle (1943) and others in this country to repeat their observations have been unsuccessful.

Though a number of workers have endeavoured unsuccessfully to transmit the disease to a wide variety of animals (Findlay, MacCallum and Murgatroyd 1939, van Rooyen and Gordon 1942), human volunteer experiments have been more promising. Admittedly, the results have been irregular, but there is now little doubt that an infective agent has been demonstrated in the serum, the nasopharynx, the duodenal juice and the fæces of patients in the pre-icteric or early icteric stage of the disease (Voegt 1942, Cameron 1943, MacCallum and Bradley 1944).

In discussing the ætiology of infective jaundice, it is important to draw attention to certain other types of jaundice. *Catarrhal jaundice*, which is believed to result from obstruction of the common bile duct, caused either by cholangitis or by pressure, is a sporadic, non-infective disease, and has probably no relation to infective hepatitis. Serum jaundice and arsenic jaundice, on the other hand, may be closely related to it.

Serum jaundice has been observed in man and in horses inoculated with homologous serum, usually for the prophylaxis of some disease. In 1937 a small outbreak occurred among the recipients of a single batch of measles convalescent serum (Report 1938*b*). Propert (1938) described a similar outbreak following the prophylactic use of serum for measles in an institution for mental defectives. Findlay and MacCallum (1937, 1938) in this country and Soper and Smith (1938) in the United States reported its occurrence after the use of yellow fever vaccine. In Brazil there was an attack rate of 27 per cent. among 304 persons immunized

with a particular batch of yellow fever vaccine (Fox *et al.* 1942); and during the first half of 1942 there was a very large outbreak in which 28,585 cases occurred in American troops who had received yellow fever vaccine (Report 1942*a*, *b*). In all these instances the vaccine had included human serum in its preparation. Jaundice has also followed inoculation with mumps convalescent serum (see Beeson *et al.* 1944). Observations have shown that with some batches of serum as small a quantity as 0·1 ml. may prove infective (see Bradley, Loutit and Maunsell 1944). Horses injected with immune horse serum in an attempt to prevent such diseases as grass sickness, equine encephalomyelitis, staggers, and anthrax have developed jaundice (for references see Report 1943*a*). The incubation period in serum jaundice is variable, but is usually about 2 to 3 months. The morbidity is often high. The case mortality in some outbreaks has been negligible; in others it has been considerable. There is at present little evidence to suggest that serum jaundice is contagious. Oliphant, Gilliam and Larson (1943) have shown that the serum of patients suffering from jaundice after the inoculation of yellow fever vaccine can itself give rise to jaundice when injected subcutaneously into human volunteers; and that the blood of the donor may be infective before the appearance of the jaundice, but not 2½ months after its disappearance. Moreover, icterogenic serum may give rise to jaundice when given by the mouth in gelatin capsules; the incubation period under these conditions may be as short as 30 days (see Havens *et al.* 1945). Findlay, MacCallum and Murgatroyd (1939) regard the agent of serum jaundice as a virus on the grounds that it can be propagated in tissue culture, it fails to grow on ordinary bacteriological media, it is invisible under the microscope, it passes freely through a Seitz EK filter, it withstands freezing and drying for many months at 4° C., and it gives rise to a disease characterized by an incubation period varying from 35 days to 7½ months. In this connection it may be pointed out that a long incubation period is not uncommon in some virus diseases, such as rabies, infective warts, and the disease of sheep known as scrapie, in which it may extend up to 2 years. Growth in tissue culture, however, is very doubtful, and has not been satisfactorily established.

Arsenic jaundice may occur during the treatment of syphilitic patients with salvarsan, neosalvarsan, arsphenamine, or other similar drug. Ruge (1931), whose monograph should be consulted, studied large numbers of cases in the German navy during the years 1919–29. The incubation period varied between 2 and 3 months according to the nature of the arsenic preparation used. Four-fifths of the cases occurred in men under 26 years of age, and 99·5 per cent. of the cases had a negative Wassermann reaction at the time the jaundice appeared. The case incidence was higher in men on board than on shore, and in small ships than in large, suggesting overcrowding as a predisposing factor. The frequency of arsenic jaundice rose and fell almost simultaneously with that of ordinary infective hepatitis. Fresh light was thrown on the disease when it was found that infection could be transmitted from patient to patient by the use of imperfectly sterilized syringes used for intravenous inoculation. Even a trace of blood left in the syringe from an infected patient during the incubation period may suffice for this purpose (Sheehan 1944, Salaman *et al.* 1944). How far arsenic jaundice is due to the toxic action of the drug on the liver, and how far to a virus transmitted by inoculation from one patient to another—the arsenic therapy being mainly incidental—it is at present impossible to say.

Though serum jaundice and arsenic jaundice differ from infective hepatitis

in their longer incubation period and in their apparent lack of infectivity for contacts, they resemble it in several ways. The general symptomatology, the changes in the white cells of the blood, the primary necrosis of the liver (see Dible *et al.* 1943), and the negative bacteriological findings suggest that these three diseases may all be manifestations of the same primary infective agent. This view is strongly maintained by Sheehan (1944), who believes that the incubation period of epidemic hepatitis is 3 months, and not 4 weeks as is usually held.

Even though there is a difference in the usual length of the incubation period, as appears probable from numerous reliable observations, there is no justification for concluding that infective hepatitis is caused by a different virus from that responsible for serum and arsenic jaundice. In these two diseases the virus is inoculated along with serum, and it may be that antibodies present in the serum delay its multiplication. In infective hepatitis, on the other hand, the virus gains direct access to the tissues, and its invasion of the body may therefore occur more rapidly. Much active research is now in progress on this interesting group of diseases, and crucial experiments are being undertaken to determine whether a patient who has recovered from one disease is immune to either of the other two. So far as it is possible at present to draw any conclusions, we feel that the balance of evidence favours the view that these three diseases are caused either by the same agent or by closely allied agents—probably belonging to the group of filtrable viruses.

Apart from exclusion of a known pathogenic agent and of Weil's disease, bacteriology can be of little help in the diagnosis of infective jaundice. Though there may be a transient leucocytosis in the early stage of the disease, leucopenia is the rule. There is a rise in the relative proportion of monocytes, but less than that in glandular fever. The blood picture alone is often of value in the differential diagnosis from Weil's disease, in which there is a polymorphonuclear leucocytosis. A complement-fixation test with the patient's serum has given promising results, but is still too much in the experimental stage to be recommended for routine use.

Beyond the usual general measures taken to prevent the spread of respiratory infections, there is little of known prophylactic value to recommend. The duration of infectivity of the patient appears to be short, and probably two weeks' isolation is ample (see Pickles 1939, Edwards 1943). (For further information see Blumer 1923, Wollenberg 1926, Klemperer, Killian and Heyd 1926, Hurst and Simpson 1934, Wickström 1936, Report 1938*a*, Pickles 1939, Cullinan 1939, McFarlan 1941, 1945, Newman 1942, Findlay, Martin and Mitchell 1944.)

BARTONELLA INFECTIONS. OROYA FEVER. VERRUGA PERUANA. INFECTIOUS ANÆMIA OF RATS, DOGS, AND MICE

These diseases, which have attracted attention during recent years, are caused by minute micro-organisms intimately associated with the red blood corpuscles, and belonging either to the *Bartonella* or *Eperythrozoon* groups (see Chapter 37).

Oroya fever and **Verruga peruana** appear to be two stages of the same disease. They are limited to the tropical zone of western South America, namely Peru, Colombia and Ecuador. Owing to the widespread epidemics that may occur and the high case mortality of the disease—somewhere about 40 per cent.—Oroya fever is to be regarded as one of the most serious infections of South America.

In the Colombian outbreak of 1938, 4,000 deaths occurred among a total population of 100,000 (see Weinman 1944).

Oroya fever, sometimes known as Carrión's disease, is characterized by fever and a severe progressive anæmia, the red cell count sometimes falling within a few days to 1 million per c.mm. Examination of the blood shows the presence in the red corpuscles of small rod, dumb-bell, and coccoid bodies, varying considerably in number and staining red or reddish-purple with Giemsa. The organisms can be cultivated on semi-solid nutrient media. Inoculated intravenously into young *rhesus* monkeys, pure cultures of *Bartonella bacilliformis*, but not infected blood, give rise to an irregularly remittent type of fever, sometimes accompanied by severe anæmia. The incubation period of the disease is usually about 20 days. In fatal cases death occurs as a rule in 3 to 4 weeks. In patients that recover, convalescence is established after about 5 or 6 weeks, but is often succeeded in a month's time by an eruption of verruga. Second attacks of Oroya fever appear to be uncommon.

Verruga peruana is a disease characterized by the appearance on any part of the body surface of vivid red wart-like eruptions. The disease follows a short time after an attack of Oroya fever, and lasts as a rule for 4 to 6 months. Second attacks may occur, and sometimes a latent infection persists after the subsidence of the skin lesions. The case mortality is very low. There is generally a moderate degree of anæmia, but the parasites in the blood are too few to be seen microscopically, though they can often be revealed by culture. *Bartonella* can be readily cultivated from the local lesions, and can be seen microscopically in stained sections of the excised tissues. Pure cultures, or juice from the nodules, inoculated intradermally above the eyebrow of monkeys give rise after an incubation period of 9–20 days to a local verruga papule. Experimental infection is followed by immunity. In the monkey the spleen appears to play no part in the defence mechanism of the host, such as it does in the rat infected with *Bartonella muris*.

Both Oroya fever and verruga appear to be carried by sandflies, such as *Phlebotomus noguchi* and *Phlebotomus verrucarum* (Shannon 1929, Hertig 1937). In endemic areas latent infections in man appear to be not uncommon (Weinman and Pinkerton 1937). The blood of patients suffering from the disease may contain agglutinins to *Bartonella bacilliformis* in a titre of 1/10 to 1/80 (Howe 1942). Organic arsenic compounds have no curative effect. (For further description see Noguchi 1926, Kikuth 1931, 1934, Pittaluga 1938, and a comprehensive review by Weinman 1944.)

Infectious Anæmia of rats, caused by *Bartonella muris*, is a disease that is precipitated by splenectomy. With the exception of certain breeds, such as the Wistar strain, a large proportion of adult rats, both wild and tame, appear to suffer from a latent infection with this organism. In such animals removal of the spleen is followed, usually in 4 or 5 days, by general illness, emaciation, and a severe progressive anæmia. Frequently hæmoglobinuria develops and the animal dies, generally within 14 days. Recovery may, however, occur, but it is liable to be followed by relapses at irregular intervals. Examination of the blood during the acute stage of the disease reveals a high proportion of red cells infected with *Bartonella* (Fig. 213, p. 904). The organisms have been cultivated successfully on leptospiral and other media. In animals that recover they disappear from the blood in 1–5 weeks. Splenectomy in young rats that have not yet become infected with *Bartonella* is without effect, but if a pure culture or infected blood is injected into a splenectomized animal then typical anæmia develops. Inoculation of a

non-infected non-splenectomized animal produces only a mild anæmia. The disease can also be reproduced in young rabbits, guinea-pigs, and white mice by inoculation.

The part played by the spleen is decisive, though in what way it acts is still a matter of conjecture. A quarter of the spleen left *in situ* is sufficient to protect the animal against the disease (Perla and Marmorston-Gottesman 1930). Perla and Marmorston-Gottesman (1932) have prepared an aqueous lipoid extract of the spleen that neutralizes the effect of splenectomy. The same workers find that if rats are fed prior to splenectomy on a diet containing an adequate amount of iron and copper, a large proportion of them fail to develop anæmia. Sandberg and Perla (1934) have shown that splenectomy in non-infected albino rats is followed by an increased retention of iron but an increased elimination of copper. The suggestion is therefore that the spleen plays an important part in the utilization of copper, and that in animals on a normal diet the amount of this substance is insufficient to prevent the development of a severe anæmia if the spleen is removed. Certain trypanosome infections, poisons such as toluylenediamine, pyridine, and phenylhydrazine (Lauda and Marcus 1928), irradiation, and possibly some bacterial infections, may activate a latent *Bartonella* infection even in the presence of an intact spleen.

Natural infection is probably carried by rat lice. Neosalvarsan administered before splenectomy prevents the development of anæmia. Administered after the disease has developed, it has a marked therapeutic effect. Certain arsenic-antimony compounds are said to be even more effective. According to Emery (1940), sulphanilamide has no therapeutic action. (References: Mayer 1921, Ford and Eliot 1928, Eliot and Ford 1929, Perla and Marmorston-Gottesman 1930, 1931, 1932, Marmorston-Gottesman and Perla 1930, 1931, 1932*a*, *b*, Lwoff and Vaucel 1931, Roth 1932, Kikuth 1934, McCluskie and Niven 1934.)

Infectious Anæmia of dogs is caused by *Bartonella canis*. The organisms were first observed by Kikuth (1929) in the blood of a splenectomized dog. The course of the disease resembles that in rats. The parasites multiply up to a certain point, then suddenly disappear from the peripheral blood, only to reappear after a few days and again work up to a maximum. Remissions of this type may occur for months. The length of the relapses and of the remissions varies from dog to dog (Regendanz and Reichenow 1932). The anæmia is seldom severe; death is infrequent; and spontaneous recovery leaves behind it a substantial degree of immunity. Infection appears to be transmitted from dog to dog by fleas. Neosalvarsan exercises a specific effect on the course of the disease. At the height of the disease *Bartonella canis* is present in very large numbers. It is said by Regendanz and Reichenow to be situated extracellularly. This may account for the fact that the parasites may suddenly disappear from the blood without any serious diminution occurring in the number of red blood corpuscles. The organisms are very pleomorphic, and may become agglutinated into characteristic masses or chains at the periphery of the cells. Cats, as well as dogs, are susceptible to experimental inoculation after splenectomy (see also Pérard 1929, Lwoff and Provost 1929, Kikuth 1934).

HYPEREMESIS HIEMIS: THE WINTER VOMITING DISEASE: EPIDEMIC NAUSEA AND VOMITING

The winter vomiting disease has been met with in many countries. Outbreaks have been reported by Zahorsky (1929, 1940) in the United States, by Rischel

(1935) and Henningsen (1936) in Denmark, and by Miller and Raven (1936), Gray (1939), and Bradley (1943) in Great Britain. It is possible that the outbreak of gastro-enteritis described by Smith and Davies (1941) was an example of the same disease. Whether it is related to the vomiting sickness of Jamaica, which was ascribed by Scott (1916) to poisoning by achees, is very doubtful, but in view of the benign nature of the winter vomiting disease and the high case mortality of the Jamaican sickness, this seems improbable. Zahorsky first experienced an epidemic at St. Louis in 1904. He observed it during many subsequent winters. The last outbreak he describes was at St. Louis in 1940, when fully 3,000 children were attacked during the first three weeks of February. A similar outbreak at Charleston, S.C., reported by Waring (1942), affected several thousand persons during February and March 1941. All ages are attacked, but infants and young children seem to be specially susceptible. The incubation period is thought to be 2 to 7 days. The onset of the disease is often abrupt, but it may be preceded by abdominal pain or nausea for a day or two. The vomiting is violent, forcible, and often projectile. It lasts for a day or two, and may lead to a state of collapse. Soon after its commencement diarrhœa, accompanied sometimes by colicky pains, sets in. It is seldom profuse, though it may be so. The stools are thin, pale in colour, and very offensive. A temperature of 99°–100° F. is not uncommon. Children sometimes appear profoundly ill. They remain, without food, in a listless or semi-comatose state for 2 or 3 days. Death, however, is rare. A mild inflammation of the upper respiratory tract is often present. The leucocyte count tends to be raised. The clinical diagnosis is made on the presence of an epidemic, persistent vomiting, offensive light-coloured stools, the relatively afebrile course, and the absence of an acute respiratory infection or otitis media. The cause of the disease is unknown. Our own observations, like those of others, have failed to reveal the presence of any known pathogenic organism. The practical absence of cells from the stools suggests that the disease is not primarily an enteritis, nor do epidemiological studies point to a food-borne infection. It seems more probable that infection occurs through the respiratory tract. Zahorsky (1940) distinguishes it from influenzal gastritis, since it may supervene explosively on an outbreak of this disease.

INFECTIOUS CATARRH OF MICE

Nelson (1937) has described a disease of mice characterized by rhinitis, otitis media, and a terminal lobar pneumonia. Infection spreads readily by contact, progresses slowly, but ultimately proves fatal. No nasal discharge is visible externally, but a copious semi-fluid white exudate can be withdrawn from the nostrils by a capillary pipette. The disease can be readily transmitted to normal mice by instillation of exudate from the nose, ear or lung. Microscopical examination of nasal or ear discharge reveals the presence of small Gram-negative coccobacilliform bodies, 0·3–0·4 μ in diameter, arranged singly, in pairs, or small groups, and predominantly extracellular. The organisms cannot be cultivated on ordinary media, but can be grown in tissue culture. Nasal instillation of pure cultures reproduces the disease in mice. The coccobacilliform bodies are similar to those found by Nelson (1936) in fowl coryza. Whether infectious catarrh of mice is allied to the so-called mouse-influenza described by Kairies and Schwartzer (1936) in Germany is not known.

CHAPTER 80

RELAPSING FEVER, AVIAN SPIROCHÆTOSIS, AND VINCENT'S ANGINA

RELAPSING FEVER

SYNONYMS : Famine fever ; tick fever.

RELAPSING fever is the name given to a disease the chief characteristic of which is the occurrence of one or more relapses following the subsidence of the primary febrile paroxysm. It would perhaps be more correct to define it as a general term for a group of closely allied diseases ; for relapsing fever differs in its symptomatology in different countries. The disease is widespread in Eastern Europe, in Asia, in Egypt, and along the North African coast, in Mexico, and in Central and South America. It used to occur in this country and in Ireland, particularly during times of famine ; the last epidemic was in 1868–71. In the United States the earliest record is of an outbreak in Philadelphia in 1844 among immigrants from Liverpool. Further outbreaks among immigrants were recorded in New York in 1847 and 1871, and in Philadelphia in 1869 (Moursund 1942). There was an outbreak in 1874 among Chinese labourers in California, though according to Meyer (1936) this was more probably typhus fever. The first indigenous cases were recognized in 1915 in Colorado ; since then there have been numerous reports of the disease in the south-western States including California. (For epidemiology in United States, see Report 1942.) The tick fever of Central Africa was shown simultaneously by Ross and Milne (1904) and Dutton and Todd (1905) to be a form of relapsing fever. The incubation period is from 2 to 10 days as a rule, sometimes as long as 14 days. The mortality is generally low—less than 6 per cent.—but in some epidemics it has been as high as 30 per cent. The causative organism of the disease was first observed by Obermeier in the Berlin epidemic of 1867–68 ; his observations were published in 1873 (Obermeier 1873). He noticed the presence of thread-like bodies in the blood of patients during the febrile stage of the disease, the disappearance of these bodies during the afebrile stage, and their reappearance during the relapse. By reason of their motility and their wave-like spiral form, he considered them to belong to the group of Spirochætes. In the blood they occurred as straight forms, S-forms, and even as circles ; towards the end of the paroxysm he noticed their tendency to aggregation in rosettes and their granular disintegration. The organisms occurred only in patients with relapsing fever ; they were never found in the blood of normal persons, or of patients suffering from other fevers. These observations are of considerable historical importance, because they were among the first to establish the microbial theory of infection.

The spirochæte described by Obermeier is known as *Treponema recurrentis*, and is the usual type found in European relapsing fever. Besides this, a number

of other spirochætes have been described associated with relapsing fever in other countries; and, as these exhibit certain differences, particularly in their antigenic structure, their virulence to various laboratory animals and, perhaps most important of all, their specificity for their intermediate host—the louse or the tick—they have been regarded by some workers as separate species and named accordingly. Thus we have *Trep. duttoni* of Central Africa, *Trep. novyi* of North America, *Trep. kochi* of East Africa, *Trep. carteri* of India, *Trep. persicum* of Iran, *Trep. usbekistanicum* of Russian Turkestan, *Trep. sogdianum* of Palestine, *Trep. hispanicum* of Spain, *Trep. venezuelense* of South America, and a few more. Other workers, however, regard all these organisms as varieties of the same species.

As seen by dark-ground illumination in the blood of patients during a febrile paroxysm, they are actively motile spiral organisms, with a series of five to ten fairly regular but loose primary waves; during rest their axis is generally straight, but when in motion they momentarily assume various curved and bizarre forms. Their length is variable, and differs with different species; generally it is 10–20 μ. The spirals are 2–3 μ long, and about 1 μ in amplitude. Division occurs by transverse fission; during this process a constriction appears at the middle, and the two organisms draw apart, leaving a thin thread-like connection between them. After separation has occurred, this remnant of the periplast may often be seen attached to one end; by many workers it has been described as a flagellum. Under suitable conditions the organisms are extremely motile, darting rapidly across the field; but in ordinary wet blood films their motion is slower; they move backwards and forwards over a distance of not more than two or three times their own length (Novy and Knapp 1906). Rotation occurs around the long axis. The numbers present in a blood film vary from case to case; at the height of the first pyrexial attack they are often numerous—several organisms to a field—but they may be relatively few and difficult to find. During the decline of the fever their numbers diminish, the organisms become less motile, and not infrequently they assume irregular shapes or accumulate in rosettes (see Fig. 215, p. 913); these changes are regarded as indicative of lysis or agglutination due to the action of antibodies developing in the host. After the subsidence of the fever they can no longer be found microscopically in the blood; there is evidence, however, to suggest that a few organisms may persist in the blood, since inoculation of blood into animals during the apyrexial interval may give rise to infection. At the onset of the relapse they again become demonstrable microscopically in the blood, though not always in such large numbers as in the first attack. During the interval between the pyrexial attacks the organisms remain latent in the tissues. Experiments conducted on mice suggest that the brain is one of the organs in which infection frequently persists (Heronimus 1928).

The spirochætes are best demonstrated by dark-ground illumination; but they may be stained by methylene blue, or preferably by Leishman or Giemsa, with both of which they take on a bluish colour. If the blood films are made in the usual way and allowed to dry in air, the organisms undergo gross distortion and present irregular and coiled forms; if their natural form is to be preserved, they should be wet-fixed.

Transmission of the Disease.

Relapsing fever is transmitted by blood-sucking insects. Dutton and Todd (1905) showed that the tick fever of the Congo Free State was spread by the tick

Ornithodoros moubata; infected ticks were able to transmit the disease to monkeys, and in one experiment young ticks, newly hatched in the laboratory from eggs laid by infected parents, successfully conveyed the disease to monkeys, showing that the infection could be transmitted hereditarily. In Uganda, Ross and Milne (1904) brought evidence to show that the disease was spread by the bite of the tick *Ornithodoros savignyi*. In Panama and South America it is spread by the ticks *O. talaje* and *O. venezuelensis*, in Texas by *O. turicata*, in California by *O. hermsi* and *O. parkeri* (see Davis 1942), in Spain by *O. marocanus* and *O. erraticus*, and in Iran and Palestine by *O. papillipes* (see Delpy and Rafyi 1939). The method by which the tick transmits infection is still subject to doubt. It is generally assumed that the infected fluid exuded by the coxal glands contaminates the wound made by the bite of the tick. In some ticks, however, such as *O. hermsi* and *O. turicata*, the coxal fluid is not infective (Herms and Wheeler 1936, Francis 1938), and infection probably results from the bite itself, particularly from bites of the larvæ. After a good meal of blood, ticks may survive starvation and remain infective for as long as five years (Francis 1938). The mammalian reservoir of infection is constituted by a variety of animals, especially rodents, but including pigs, porcupines, opossums, and armadillos (see Sautet 1937).

Though the disease in Central and South Africa, in North and South America, in Palestine and Iran, and some other parts of the world is spread by ticks, in most of Europe and Asia the chief vector is the louse (Wenyon 1926). The organisms may be demonstrated for 24 hours in the stomach of the louse following an infective feed; after this time they can no longer be found; but in about 6 or 8 days they reappear in the fluids of the body cavity, and spread to all parts of the body including the legs and antennæ. Infection is conveyed to human beings not by the bite of the louse, which appears to be harmless, but by contamination of the wounds, made by biting or by scratching, with the body fluids of the louse. In ticks, Wheeler (1942), working with *O. hermsi*, found that the spirochætes invaded the cœlomic cavity within three days of being ingested, and by the tenth day were demonstrable in the muscles. In contrast to ticks, hereditary transmission of infection has never yet been satisfactorily demonstrated in lice. Occasionally human beings are infected by contamination of a wound, or even of the nasal or conjunctival mucosa, with the blood of an infected animal. Laboratory infections of this kind are not uncommon.

Immunity.

The disappearance of the spirochætes from the blood stream at the end of the first pyrexial attack has been regarded by many workers as due to the development of antibodies. This view has to some extent been substantiated by the work of Novy and Knapp (1906).

Working with the rat, they found that the organisms would live in defibrinated blood kept at room temperature for 30 or 40 days, provided the blood was removed from the animal during the early stage of infection; if it was taken during the later stages, they died in 24 hours. When the organisms were examined *in vivo* during the decline phase of the infection they were observed to become sluggish, to show end-to-end agglutination, and even to form small tangles. This was even more marked when blood from an immune animal was inoculated into an infected rat; half an hour later the spirochætes were accumulated in tangled masses of 10 to 20 members, and showed end-to-end agglutination; 1 hour later they were agglutinated into perfect radiating rosettes, and 2 hours

later they were very scarce and were mostly immobile. Blood serum from a rat, which had been hyperimmunized by a course of 26 injections of infective blood, had marked immobilizing and agglutinative properties, even when diluted to 1/100. In rats that had recovered naturally from infection Pfeiffer's phenomenon could be produced *in vivo*. Intraperitoneal injection of infective blood into such animals was followed by agglutination and granular degeneration of the spirochætes; in 10 minutes no free spirochætes could be found. The altered organisms were rapidly ingested by phagocytes. In hyperimmunized rats the spirochætes completely disappeared from the peritoneal cavity in 2 minutes. In passively immunized rats the spirochætes were agglutinated into rosettes, but later these broke up, and free organisms once more became numerous; the animals, however, did not contract infection. The course of antibody production in human beings seems to resemble that in experimental animals (see Cunningham and Fraser 1935).

From these and other experiments, it would appear that during the course of the natural disease immune bodies—chiefly agglutinins, spirochætocidins and lysins—are developed, which are sufficiently powerful to overcome the blood infection and lead to the disappearance of the spirochætes from the circulation. These organisms remain latent in the brain and other tissues, and when the circulating antibodies have decreased, they once more enter the blood and give rise to a relapse. This stimulates the production of fresh antibodies, which again lead to the disappearance of spirochætes from the blood. After one or more relapses the active immunity developed by the host is sufficient to prevent further invasion of the blood by the spirochætes, and an apparent cure results. Whether a true cure results, in the sense that the body is completely rid of spirochætes, is doubtful. Animal experiments suggest rather that, even though the organisms give no token of their presence, they may yet remain alive in the tissues for weeks or months. Immunity in relapsing fever appears to be an infection-immunity; this corresponds to a state of the host in which, together with a humoral immunity, there is a latent infection of the tissues, which is capable under certain conditions of breaking down the existing immunity (Heronimus 1928). It is a state in which a working equilibrium is established between host and parasite, and like other equilibria is liable to disturbance (see Chapter 51).

There is a considerable amount of evidence to show that after the first attack the spirochætes in the tissues undergo an antigenic change which renders them insusceptible to the antibodies produced by the host against the original strain. This enables them to invade the blood a second time and give rise to a relapse. The production of antibodies to the so-called "relapse" or "serum-fast" strain is followed by the disappearance of the organisms from the blood once more. A further antigenic change may occur in the tissues enabling the organisms to invade the blood for a third time. In some instances it appears that the relapse strain reverts to the parent type, and if the circulating antibodies generated during the first attack have diminished sufficiently, another invasion of the blood may occur (Aristowsky and Wainstein 1929*a*).

It will be understood that the antigenic specificity of the relapsing fever spirochætes is highly developed. This accounts not only for the fact that patients who have been infected with one type of relapsing fever, for example the European, can be infected with another type, such as the Indian or African, but that, as just noted, a patient who has recovered from invasion with a given strain is liable to suffer from a relapse due to an antigenic variant of the same strain.

Reproduction of the Disease in Animals.

Infection can be transmitted to monkeys, rats, and mice and, with some types of spirochæte, to guinea-pigs; rabbits are usually refractory. In monkeys the disease runs much the same course as in man; 2 or 3 days after subcutaneous inoculation with the patient's blood a pyrexial attack occurs, lasting for 3 or 4 days; two, three, or four relapses may occur at intervals of 2 to 8 days, each relapse lasting from 1 to 4 days (Norris *et al.* 1906). After intraperitoneal inoculation of mice the organisms appear in the blood within 24 hours, and persist for 3 to 4 days; they then disappear for several days, after which a relapse may occur; three or four relapses may follow each other, separated by an interval of about 7 days (Novy and Knapp 1906). Sometimes the animals die after 4 or 5 days. As many as 10 to 50 organisms may be present per field during the first infection, but in the relapses only 1 or 2 organisms are seen as a rule. Intraperitoneal inoculation of white rats is followed by the appearance of spirochætes in the blood in about 40 hours; they disappear about 2 days later. The spirochætes are found not only in the blood, but in all the organs of the body. Infection is never fatal. Novy and Knapp (1906) state that rats do not relapse, though Bohls and Irons (1942) deny this. Guinea-pigs are relatively insusceptible to most strains, but are said to be easily infected with *Trep. hispanicum* and *Trep. sogdianum*, and often to die of hæmorrhagic peritonitis after inoculation with *Trep. persicum*. *Trep. usbekistanicum* is said to be uniformly fatal to them (Delpy and Rafyi 1939).

Diagnosis.

Blood should be taken during the pyrexial period and examined either by dark-ground illumination or after staining with Wright, Giemsa or gentian violet (see Beck 1936, Bohls and Irons 1942). If the staining technique is adopted, it is usually wise to make a thick film preparation by stirring 2 or 3 drops of blood on one slide with the corner of another slide till they cover an area about 1 cm. in diameter. Unless they are stained at once, they should be laked in distilled water or 1 per cent. acetic acid before staining. Thin films to be stained by Giemsa or gentian violet should be previously fixed for 3 minutes in methyl alcohol. Microscopically, the spirochætes are usually seen in large numbers in blood taken during the febrile period, but later they may be scarce and are often coiled up or clumped together.

For confirmation of the microscopical result, or for enrichment if this is negative, 1–2 ml. of fresh whole blood, or of clot ground up in saline, should be injected intraperitoneally into a susceptible animal—preferably the mouse. Spirochætes may not become visible microscopically in the mouse's blood for 2 to 3 days, and sometimes for much longer. A drop or two of blood from the tail should be examined every day for at least a fortnight from the second day onwards, if the animal does not die of the infection.

Spirochætes may sometimes be demonstrated by animal inoculation in the blood of patients for weeks after the primary attack. According to Chung (1938) the urine and prostatic fluid are sometimes infective. In making rodent surveys, the spleen, heart, or brain tissue should be ground up in saline and inoculated subcutaneously into white mice; the blood is then examined daily for spirochætes in the usual way. It is worth noting that the Wassermann reaction may be positive in relapsing fever. A method of diagnosis by serological means has been described (Stein 1944).

Prophylaxis and Treatment.

Little can be done by the individual to protect himself against infection in an endemic area beyond avoiding lice or ticks. Inoculation of living cultures, or sometimes of cultures killed by heating to 60° C. for 30 minutes, is said to give rise to the production of lysins. Persons so vaccinated may apparently resist infection with small doses of living spirochætes (Aristowsky and Wainstein 1929*a*, *b*). Whether vaccination is likely to be of value in practice it is as yet impossible to say. Like most spirochætal diseases, relapsing fever is readily cut short by injection of salvarsan or neoarsphenamine. A single suitable dose often suffices to cure the disease and prevent relapses (Wenyon 1926). However, just as " serum-fast " variants may develop during the course of the disease, so " arsenic-fast " strains may be encountered, which are little affected by salvarsan. Infections with such strains may be treated by sodium potassium bismuth tartrate (Todd 1930). The serum of convalescent patients may be used therapeutically, but little information is available about the value of this method of treatment. More recently, *Trep. recurrentis* has been reported to be susceptible to penicillin (Lourie and Collier 1943), so that in future resistant cases of the disease may perhaps prove amenable to treatment with this substance.

AVIAN SPIROCHÆTOSIS

In 1891 Sakharoff described a disease of geese that appeared every year in certain stations on the Transcaucasian railway, and resulted in a high mortality —80 per cent. Examination of the blood revealed the presence of spirochætes closely resembling those of human relapsing fever. Clinically, the infected goose went off its feed, remained apathetic in a sitting-down posture, and died of exhaustion after a week or more ; sometimes it developed diarrhœa, and its joints became affected. Post mortem, there was fatty degeneration of the heart and liver ; the liver moreover showed miliary yellowish granules of caseous consistency ; the spleen was soft and friable. During life actively motile spirochætes were found in fairly large numbers in the blood at the beginning of the disease ; later they collected into ray-forms, and finally into tangled ball-like masses. Before death they disappeared from the blood and at post mortem they could be found neither in the blood nor in the organs. Subcutaneous inoculation of infected blood reproduced the disease in normal geese after an incubation period of 4 or 5 days.

Working with the spirochæte of goose septicæmia—*Treponema anserinum*—Gabritschewsky (1898) found that if the blood serum of a goose, which had recovered naturally from the disease, was mixed with the blood of an infected goose, the spirochætes were killed in a few minutes at 37° C. ; if no immune serum was added, they lived for 18 hours. When the serum was heated to 60° C., its bactericidal power was destroyed completely. Further experiments showed that, while blood serum from a peripheral vein or from the right side of the heart killed the spirochætes in half an hour or less, juice sucked from the viscera—spleen, liver, kidney, and bone-marrow—did not kill them for 2½ to 9 hours. He also found that, in infected geese, spirochætes could still be demonstrated in the internal organs after they had disappeared from the blood. He concluded therefore that the spirochætes were destroyed in the blood by the spirochætocidins, but remained latent in the viscera where the antibodies appeared to be less concentrated. This conception of immunity is similar to that reached in the case of human relapsing fever.

As well as the spirochætocidins, there are also lysins present in the blood, and agglutinins, which are responsible for the clumping of the organisms. Phagocytosis occurs, apparently as a secondary phenomenon, after the death or immobilization of the spirochætes, though according to Himmelweit (1933) it plays an active part in the destruction of the living organisms. Gabritschewsky further showed that naturally recovered geese remained immune to further infection, as long as bactericidins were present in the blood. Antispirochætal serum, prepared by the inoculation of horses, had marked protective properties when injected into geese simultaneously with, or 24 hours after, injection of spirochætal blood; but once the organisms had appeared in the blood stream, it had no effect. That is to say, the serum had prophylactic, but not therapeutic properties. By injection of normal geese with a single dose of immune serum, followed on the next day by injection of spirochætal blood, he succeeded—by active immunization under cover of a passive immunity—in rendering the birds highly resistant to the disease. This method he recommended for combating natural outbreaks of the disease.

More widespread than the disease in geese is **spirochætosis of fowls,** which was first described by Marchoux and Salimbeni (1903) in Brazil, and later by Balfour (1908) in the Sudan. The symptoms and general course of the disease appear to be much the same as in geese.

The disease can be transmitted by subcutaneous, intramuscular, or intraperitoneal injection of hens with infected blood; the bird develops diarrhœa, the temperature rises to 43° C., and spirochætes appear in the blood in 24 hours. The temperature falls after 3 or 4 days to 40° or 41° C., but the organisms continue to increase in the blood. Later, however, they become aggregated into groups, their movements become slower, and they form figures of 0 and 8. At this stage the bird dies, though sometimes a chronic disease develops, lasting for about a fortnight, and followed by death. The disease can be transmitted to fowls, geese, ducks, guinea-fowls, and sparrows; pigeons are fairly refractory, monkeys and guinea-pigs completely so (Marchoux and Salimbeni 1903). Neither in the goose nor in the fowl do relapses occur; the bird either dies or recovers completely.

The natural disease is spread by ticks. In Brazil *Argas miniatus* was found to be responsible; in the old world *Argas persicus* is the tick that has been chiefly incriminated. Marchoux and Salimbeni (1903) found that ticks might remain infective for 5 months after biting a diseased fowl. According to Hindle (1912) ticks may transmit the infection to their progeny, and these again to the next generation, without having had an infective feed in the meantime.

The disease occurs in **ducks** as well as in fowls and geese. It is probable that the causative organism is the same in each species; its proper name therefore is *Treponema anserinum* (Wenyon 1926). Those anxious for further information on avian spirochætosis are referred to the monograph of Knowles, Gupta, and Basu (1932) who, besides giving a bibliographical review of the subject, have made a number of observations themselves, particularly on the mechanism by which immunity develops.

Blood Spirochætoses in other Animals.

Cattle suffer from a spirochætosis caused by *Treponema theileri*; infection is conveyed, at least in South Africa, by the tick *Margaropus decoloratus*. A similar disease in horses and in sheep, probably due to the same organism, *Trep. theileri*, has also been reported by Theiler in South Africa. Spirochætes of the relapsing fever type have been observed in the blood of elephants, camels, antelopes, monkeys, and some other mammals (Wenyon 1926).

VINCENT'S ANGINA AND CERTAIN RELATED INFECTIONS

There are certain necrotic and gangrenous infective processes in human beings, such as ulcero-membranous gingivitis, hospital gangrene, noma, fœtid bronchitis, and gangrenous laryngitis, in which spirochætes have frequently been demonstrated. Of these, one of the chief is the so-called spirillum described by Vincent (1896, 1899), now known as *Treponema vincenti* (see Chapter 38). It is not clear whether Vincent's spirillum is responsible for the necrotic lesions in which it is found, or whether it is a mere secondary invader. The fact that it is often present in scrapings of the gingivo-dental fold in apparently healthy mouths has led many observers to doubt its ætiological rôle in the inflammatory diseases just mentioned. Black (1938), for example, found Vincent's spirillum in 60 per cent. of children under 12 years of age, fusiform bacilli in 94 per cent., and both together in 18–63 per cent. according to age. He regards these organisms as members of the normal flora of the mouth, which multiply when conditions are favourable, but which are without pathogenic action. Recent work (see p. 1897) has shown that some of the gingivo-stomatitis of children is a primary herpetic infection; but there is nevertheless a group of diseases characterized by ulceration of the gums and throat, in which no virus has so far been demonstrated, but in which Vincent's spirilla are abundant. The organisms are often found associated with a characteristic fusiform bacillus, likewise described by Vincent (1896, see Chapter 18). It has been suggested (Tunnicliff 1906) that *Trep. vincenti* and the fusiform bacillus represent two phases of the same organism; but the balance of evidence is definitely against this view. Since we know that strict anaerobes are unable to grow in healthy tissue, the finding of large numbers of spirochætes and fusiform bacilli in swabs taken from the ulcerated gums is an index of the presence of necrotic tissue or of non-living matter in the mouth. In fact, the disease is often associated with septic teeth, salivary calculi, or an erupting third molar. Why the disease becomes almost epidemic in war-time is still unknown. Shortage of ascorbic acid or of nicotinic acid in the diet has been suggested, but the evidence is not convincing. Infection from one person to another in camps or communal feeding centres probably plays some part. Arsenic has been used in treatment, but its value is doubtful. Measures directed to cleaning up the mouth, the removal of dead tissue, and of tartar on the teeth, and the use of hydrogen peroxide washes and zinc peroxide pastes seem to be more effective. Penicillin is reported to be of benefit.

Treponemata have also been isolated from the sputum of tuberculous patients (Bezançon and Etchegoin 1926), and from other bronchial and pulmonary lesions (Bacigalupo 1928); but we know nothing with regard to the relation of these organisms to each other or to *Trep. vincenti.*

CHAPTER 81

SYPHILIS, RABBIT SYPHILIS, AND YAWS

SYPHILIS

THE origin of syphilis is not definitely known, but its presence in Europe is said to date from the end of the fifteenth century, when it was brought to Spain by Columbus's sailors returning from the New World. The disease spread rapidly over Europe, and was at first endowed with the malignancy that is characteristic of most infective diseases on first reaching virgin soil. Now, after centuries of endemic prevalence, the disease is much milder; this is probably due in part to better and more rapid treatment, and in part to the development of a racial immunity, similar to that which appears to have developed against tuberculosis.

Edwin Klebs in 1875–77 was apparently the first to see spirochætal bodies in syphilitic material and to transmit the disease to monkeys (see A. C. Klebs 1932). Haensell in 1881 produced a local lesion in rabbits by inoculation of the eye. Metchnikoff and Roux (1903, 1904*a*, *b*, 1905) transmitted the disease to apes, and found that chimpanzees developed not only primary but also secondary lesions following inoculation with human syphilitic material. In 1905 Schaudinn and Hoffmann discovered the causative organism of the disease. In chancres and in the inguinal glands of syphilitic patients they demonstrated a spirochæte, now known as *Treponema pallidum*, which occurred both on the surface and in the depth of the tissue. They stained it by a modified Giemsa stain, and described its characteristic morphology and movements. In chancres it was frequently accompanied by another spirochæte—*Trep. refringens*—which was broader, less regular, and more refractile. But *Trep. refringens* was sometimes found in non-syphilitic lesions, such as gonorrhœal papillomata, whereas *Trep. pallidum* was never found except in syphilis. Though Schaudinn and Hoffmann did not decide whether *pallidum* and *refringens* were different species, it has since been shown that it is *Trep. pallidum* alone that is responsible for the causation of syphilis. (For further history see Schuberg and Schlossberger 1930, Stokes 1931, Klebs 1932.)

Bacteriology.

Syphilis is transmitted chiefly by direct, but sometimes by indirect contact. *Treponema pallidum* has the power of gaining entrance to the body through minute lesions of the skin or mucous membranes. It is, however, a very strict parasite, and its life outside the animal body is short; if this were not so, syphilis of non-venereal origin would probably be very much more common than it is. Infection may likewise be transmitted from mother to child, causing the congenital type of syphilis; this results from the passage of spirochætes through the placenta. Except in congenital syphilis, in which the disease is generalized from the

start, infection is rendered evident by the development of a primary lesion or chancre. This appears within a month of infection, and is accompanied by enlargement of the focal lymphatic glands. From 6 to 12 weeks after the appearance of the primary chancre, the secondary stage of the disease sets in; this is marked by constitutional symptoms, cutaneous lesions, enlargement of the lymph glands, and often affections of the bones, joints, eyes, and other organs. The secondary passes over insensibly into the tertiary stage, which may persist for years; this is characterized by the development of ulcerating necrotic lesions of the skin and mucous membranes and by gummata of the internal organs. Years after the contraction of the disease disorders of the nervous system may appear, such as tabes dorsalis and general paralysis; these are sometimes referred to as quaternary or parasyphilitic affections.

Up to the commencement of the secondary stage, syphilis is clinically a localized disease; bacteriologically, however, it appears probable that infection becomes generalized soon after infection. Kolle and Evers (1926*b*) infected rabbits by cutaneous or subcutaneous inoculation into the scrotum with syphilitic material, removed the inguinal glands after varying periods, and injected these into fresh animals. By this means they found that the glands were infective within 30 minutes of the scrotal inoculation. Working with guinea-pigs, they were able to show that the spirochætes reached the focal glands within 5 minutes of cutaneous inoculation of the scrotum. In apes the time elapsing between infection and invasion of the glands is probably longer; Metchnikoff and Roux (1905), for example, found that chimpanzees anointed locally with calomel ointment, 1 to 2 hours after cutaneous inoculation, never developed syphilis. Taking this experimental evidence in conjunction with the fact that local disinfective measures in human beings are comparatively valueless unless practised within an hour or two after exposure to infection, we may conclude that the spirochætes rapidly invade the tissues, even though they give no clinical sign of their presence. During the primary stage of the disease, they are found in the local chancre, and can sometimes be demonstrated in the blood. Thus, Uhlenhuth and Mulzer (1913) drew off the blood of patients with primary and secondary syphilis, defibrinated it, and injected it into the testicles and scrotum of rabbits; the whole operation was completed within 10 minutes. Syphilis developed in 67 per cent. of the animals inoculated from patients with primary, and in 70 per cent. of those inoculated from patients with secondary syphilis. Spirochætes are present in all the secondary lesions, and may be excreted in the semen (Uhlenhuth and Mulzer 1913). In the tertiary lesions such as gummata they are demonstrable, but only in small numbers; their virulence, however, appears to be maintained. Noguchi and Moore (1913) found them in the brain of patients dying of general paralysis; they were seen in all the layers of the cortex with the exception of the outer or neuroglial layer. In congenital syphilis spirochætes are distributed in large numbers throughout the viscera, particularly the liver, lungs, spleen, and suprarenals. Both in congenital and acquired syphilis the organisms may remain latent for long periods of time without giving rise to any clinical manifestations of disease.

Immunity to Syphilis.

Immunity to syphilis resembles in many respects immunity to tuberculosis; that is to say, it is an infection-immunity. So long as infection persists, and so long as living spirochætes are present in the tissues, the infected person is rela-

start, infection is rendered evident by the development of a primary lesion or chancre. This appears within a month of infection, and is accompanied by enlargement of the focal lymphatic glands. From 6 to 12 weeks after the appearance of the primary chancre, the secondary stage of the disease sets in; this is marked by constitutional symptoms, cutaneous lesions, enlargement of the lymph glands, and often affections of the bones, joints, eyes, and other organs. The secondary passes over insensibly into the tertiary stage, which may persist for years; this is characterized by the development of ulcerating necrotic lesions of the skin and mucous membranes and by gummata of the internal organs. Years after the contraction of the disease disorders of the nervous system may appear, such as tabes dorsalis and general paralysis; these are sometimes referred to as quaternary or parasyphilitic affections.

Up to the commencement of the secondary stage, syphilis is clinically a localized disease; bacteriologically, however, it appears probable that infection becomes generalized soon after infection. Kolle and Evers (1926*b*) infected rabbits by cutaneous or subcutaneous inoculation into the scrotum with syphilitic material, removed the inguinal glands after varying periods, and injected these into fresh animals. By this means they found that the glands were infective within 30 minutes of the scrotal inoculation. Working with guinea-pigs, they were able to show that the spirochætes reached the focal glands within 5 minutes of cutaneous inoculation of the scrotum. In apes the time elapsing between infection and invasion of the glands is probably longer; Metchnikoff and Roux (1905), for example, found that chimpanzees anointed locally with calomel ointment, 1 to 2 hours after cutaneous inoculation, never developed syphilis. Taking this experimental evidence in conjunction with the fact that local disinfective measures in human beings are comparatively valueless unless practised within an hour or two after exposure to infection, we may conclude that the spirochætes rapidly invade the tissues, even though they give no clinical sign of their presence. During the primary stage of the disease, they are found in the local chancre, and can sometimes be demonstrated in the blood. Thus, Uhlenhuth and Mulzer (1913) drew off the blood of patients with primary and secondary syphilis, defibrinated it, and injected it into the testicles and scrotum of rabbits; the whole operation was completed within 10 minutes. Syphilis developed in 67 per cent. of the animals inoculated from patients with primary, and in 70 per cent. of those inoculated from patients with secondary syphilis. Spirochætes are present in all the secondary lesions, and may be excreted in the semen (Uhlenhuth and Mulzer 1913). In the tertiary lesions such as gummata they are demonstrable, but only in small numbers; their virulence, however, appears to be maintained. Noguchi and Moore (1913) found them in the brain of patients dying of general paralysis; they were seen in all the layers of the cortex with the exception of the outer or neuroglial layer. In congenital syphilis spirochætes are distributed in large numbers throughout the viscera, particularly the liver, lungs, spleen, and suprarenals. Both in congenital and acquired syphilis the organisms may remain latent for long periods of time without giving rise to any clinical manifestations of disease.

Immunity to Syphilis.

Immunity to syphilis resembles in many respects immunity to tuberculosis; that is to say, it is an infection-immunity. So long as infection persists, and so long as living spirochætes are present in the tissues, the infected person is rela-

tively resistant to further infection. It is possible for a patient to develop two primary chancres, provided the second infection occurs before the development of the first chancre; but once a primary chancre has developed, further infections almost invariably fail to give rise to a primary lesion. There is evidence to suggest, however, that this resistance to superinfection is more apparent than real, in the bacteriological sense. Though the second infection gives rise to no obvious symptoms of disease, the spirochætes nevertheless appear to gain access to the body and to give rise to a latent infection of the tissues.

Experiments indicate that immunity to superinfection is limited by various factors. Truffi (1910), for example, was able in some rabbits to produce a chancre by inoculation made as late as 12 days after the primary chancre had developed. Kolle and Schlossberger (1926) found that, whereas rabbits reinfected with the same strain of spirochæte did not develop a second primary lesion, those infected with a heterologous strain frequently did so. And even when no second primary lesion developed, it was shown by inoculation experiments made with the lymphatic glands that the organisms had gained access to the tissues; by the use of cross-protection experiments in two sets of rabbits, each of which was immunized against 1 strain only, it was shown that the homologous and the heterologous strains were present side by side in the same glands. According to Uhlenhuth and Grossmann (1928) the age and the virulence of the first infecting strain are of importance; infection with a weakly virulent strain may not protect against subsequent infection with a more virulent strain. Working with apes Neisser (1906) succeeded in reinfecting 9 animals at periods varying from 44 to 301 days after the first inoculation. These and other experiments indicate that, though as a rule an infected animal is resistant to superinfection, in the sense that it does not develop clinical symptoms, it may on occasion prove susceptible; and, even when it does not, it may yet allow the penetration of the organisms into its tissues; its immunity to superinfection is largely a symptom-immunity.

Other experiments support the view that infection may occur without the production of symptoms.

Kolle and Evers (1926*a*) found, for example, that 10 out of every 100 rabbits inoculated into the scrotum failed to develop a primary chancre or to show glandular swelling. These animals were nevertheless infected; the popliteal glands from 12 of these animals were inoculated into fresh animals from 82 to 199 days after infection, and in every instance they produced infection. In such animals the organisms generally lie latent in the glands, but occasionally they become active and give rise to lesions several months later. The same authors found that if rabbits containing a deposit of bismuth in their tissues were inoculated with syphilitic material, they developed no lesions whatever; but if the bismuth was later removed by surgical means, typical syphilitic lesions developed 7 or 8 weeks later. It would appear that the effect of the bismuth was not to prevent infection but to suppress the development of lesions; the spirochætes gained access to the tissues, but remained latent till the bismuth was removed. In some animals, such as mice, inoculation with syphilitic material is usually without result; no lesions develop. Yet by inoculation experiments on rabbits it has been shown that spirochætes are present in their tissues—glands, spleen, and brain—for months after infection (Kolle and Schlossberger 1928). There is evidence that the organisms actually multiply in the tissues of the mouse; thus for 6 to 8 weeks after infection the organs frequently prove negative, but after that time, and apparently for the remainder of the mouse's life, they are positive. Yet in spite of this development in the tissues, the organisms never give rise to symptoms of disease.

Whether a true immunity both to clinical disease and to infection ever develops in rabbits is not clear. There is evidence that it may, but only in animals that have been infected for a long time.

Brown and Pearce (1921) treated rabbits with arsphenamine shortly after the development of the primary chancre, and 5 days later reinoculated them with the same strain as was originally used. Nearly all the treated animals developed chancres, whereas the untreated controls did not. This indicates that animals treated in the early stage of the disease can be rendered fully susceptible again. Chesney and Kemp (1925) obtained evidence suggesting that if treatment was begun early the animals almost always became susceptible to a second infection, whereas if it was begun late they generally proved refractory to a second infection. Further experiments (Chesney and Kemp 1926, Chesney, Halley, and Kemp 1927), however, seemed to show that the immunity to reinfection of rabbits treated late in the disease was not as complete as was originally supposed. Kolle and Prigge (1927) treated their rabbits with neosalvarsan in the late stage of the disease —75 to 250 days after infection. Reinfection gave rise to no symptoms, but inoculation experiments showed that the spirochætes had gained access to the tissues; in non-reinfected controls the tissues proved sterile. This indicates that animals treated in the late stage of the disease, and cured of infection, remain clinically immune; they develop no symptoms of disease on reinfection, but they are not sufficiently resistant to prevent the organisms from gaining access to the tissues. Uhlenhuth and Grossmann (1928) treated their rabbits with neosalvarsan in the late stage of the disease—107 to 506 days after infection. Reinfection with the homologous strain performed 3 to 10 months after treatment gave rise to no symptoms; and in only 4 out of 11 rabbits were spirochætes demonstrated in the tissues. This indicates that a certain proportion of rabbits treated in the late stage of the disease remain both clinically and bacteriologically resistant to fresh infection. Similar results have been recorded by Breinl (1935).

Resuming the general findings, it may be said that untreated rabbits in the late stage of syphilis usually show a chancre-immunity to the homologous strain, even though there is no general immunity. That is to say, their immunity is sufficient to prevent the formation of a characteristic local lesion on reinfection, but is insufficient to prevent the development of the inoculated organisms in the tissues. Syphilitic rabbits treated with salvarsan within 45 days after infection only exceptionally develop a chancre-immunity; those treated 45–90 days after infection frequently do so, while those treated later than 90 days after infection almost invariably do so. The real divergence of opinion between different workers concerns the existence of a general spirochætocidal immunity in rabbits treated in the late stage of the disease. Uhlenhuth and Grossmann (1928) are convinced that such an immunity does in fact develop, while Kolle and Prigge (1927, 1929, 1934) are as equally convinced that it does not.

It would perhaps be sententious to suggest that the truth lies somewhere between the two, and that rabbits treated in the late stage of the disease are more immune than those treated in the early stage, though not always sufficiently immune to withstand completely invasion by fresh organisms. The discrepancy between the results of the two main protagonists is probably more apparent than real. Indeed, in a more recent publication Grossmann (1933) himself brings evidence to show that, though a general immunity does develop as the result of long-standing infection, it is of comparatively short duration. (See also Chapter 51.)

How closely the immunity of human beings to syphilis resembles the immunity of rabbits is not known. Judging from clinical observations it would appear that the two are not dissimilar. There is no satisfactory evidence that a spon-

taneous cure occurs either in rabbits or in man; once the organisms have given rise to active symptoms of disease, they remain latent in the tissues for an indefinite period. Every now and again they may become active, or they may remain permanently in the latent condition. Both rabbits and man can be cured if they are treated by salvarsan in the early stage of the disease; in the later stages a complete cure is very difficult to attain. Even though in man the Wassermann reaction may be rendered temporarily negative, it frequently becomes positive again after treatment is stopped.

It is very important to know whether patients with latent syphilis are infective, but unfortunately our knowledge on the subject is scanty. Animal experiments suggest that female rabbits suffering from latent syphilis may transmit the disease to healthy bucks; but apparently no primary lesions develop as in the usual type of rabbit syphilis; the spirochætes can, however, be demonstrated in the regional glands (Kolle 1928, Albrecht 1930). Kolle thinks that syphilis in human beings is often contracted in this way. Many persons are discovered in the course of routine examination to be suffering from syphilis who never suspected it, and who never showed evidence of a primary lesion. In Kolle's view such persons may have been infected by latent carriers of the disease, and have themselves acquired a latent infection without developing the usual primary lesions.

Another view has been put forward by Levaditi (Levaditi *et al.* 1928) and his collaborators. Starting from the observation that spirochætes can only rarely be found microscopically in the focal glands of rabbits infected by the scrotal route, even though these glands are almost invariably infective to fresh animals, he supposes that the virus of syphilis undergoes a development cycle of which *Treponema pallidum* is only one of the stages. In certain rabbit lesions, particularly those that were undergoing retrogression, he observed involution forms of the spirochæte, amongst which were minute granules only just visible by the microscope. He supposes that the spirochætes pass into a finely granular stage; that these granules are more resistant to arsenic and its compounds; and that they are responsible for latent infections in syphilis, and possibly for certain cases of tabes and general paralysis in which spirochætes cannot be demonstrated. Similar hypotheses have been put forward by other workers, but the evidence in their favour is unsatisfactory. Van Haelst (1933), who has carefully studied the question, finds that the successful transmission of infection to rabbits is to a considerable extent determined by dosage. The inability to demonstrate spirochætes in tabes may quite possibly be due to the very small number present in the tissues. If there is an ultramicroscopic phase of the organism, then filtrates of virulent organs should prove infective; but according to Levaditi's own findings they do not.

Diagnosis.

In the primary stage of the disease, *Trep. pallidum* may be demonstrated in the chancre. The superficial part of the lesion should be cleansed by gentle swabbing with saline, and exudate should be drawn from the base of the chancre for examination; this may conveniently be obtained by applying a small suction-cup with the usual rubber-ball attachment. The serous exudate should be examined under dark-ground illumination. The morphology of *Trep. pallidum* is described on p. 915. The eye-piece micrometer devised by Barnard (1923), with which an approximate measurement of the spirals can be made with ease and rapidity, forms a most useful aid in the identification of this organism. According to Goldsworthy and Ward (1942), dark-ground illumination may be replaced by a simple stain, such as Victoria blue 4R, or carbol gentian violet in conjunction with the Fontana mordant.

It cannot be too strongly emphasized that the identification of *Trep. pallidum* in a primary chancre requires the expert knowledge which comes only with long experience. It depends on the recognition of fine differences in morphology, without the assistance of characteristic differences in staining reaction, or of confirmatory tests on pure cultures. It is fortunate that the primary penile chancre provides the large majority of cases which the bacteriologist is called on to examine, since the spirochætal flora in such lesions is usually not copious, and consists mainly of species, such as *Trep. refringens*, which are readily differentiated from *Trep. pallidum*. Chancres in other situations, such as the lip, or primary genital chancres in the female, are far more likely to show a complex spirochætal flora, including species closely resembling *Trep. pallidum* ; and, in such cases, the greatest caution should be observed in basing a diagnosis of syphilis on a microscopical examination alone. It happens that a penile chancre usually leads to a suspicion of syphilis at an earlier stage than a genital chancre in the female, or an extra-genital chancre in either sex ; so that the latter lesions tend to be overlooked in the early stages, and, by the time they have attracted attention, the infection has usually reached the stage at which the Wassermann reaction is positive, thus providing a most valuable check on the result of the direct microscopical examination.

In the early stage of the disease it is possible to demonstrate spirochætes in excised lymph glands by inoculating them intratesticularly into rabbits, and following the progress of infection in these animals by the Kahn test and by dark-ground examination of the emulsified testicle. Negative results, however, are often obtained in treated cases and even in old untreated cases (Lake and Bryant 1930). The method is of academic rather than of practical interest.

Diagnostic Serum Reactions.

The serum reactions employed in the diagnosis of syphilis have, on account of their clinical importance, been submitted to detailed and extensive study, out of all proportion to their general immunological interest. The literature is correspondingly copious and diffuse, and it is quite impossible to review it here, or to attempt any discussion of the various points at issue. We can give only a brief description of some of the available tests and a short discussion of their interpretation.

The Wassermann Test.—Wassermann, Neisser and Bruck (1906), and Wassermann, Neisser, Bruck, and Schucht (1906) described a complement-fixation reaction, using as an antigen a watery extract of the liver of a syphilitic fœtus. This test

was found to give positive results in persons suffering from syphilis, and negative results in normal controls. The syphilitic liver was selected as a convenient source of *Trep. pallidum*, which had not then been cultivated ; and the reaction was at first supposed to be specific in the bacteriological sense. It was soon found, however, that this was not the case (Marie and Levaditi 1907), since extracts of normal liver gave identical results. Still better results were obtained when watery extracts were replaced by alcoholic extracts of various tissues, and it was shown that the reacting substance was contained in the lecithin fraction of the lipoids, which is soluble in alcohol but insoluble in acetone (Porges and Meier 1908). This so-called " antigen " is rendered more sensitive, as regards its reaction with syphilitic sera, by the addition of an alcoholic solution of cholesterol (Browning and Mackenzie 1924). The antigen most commonly employed at the present time is an alcoholic extract of heart-muscle from the ox, calf, or man, from which the acetone-soluble fraction has been removed. To this alcoholic extract is added an alcoholic solution of cholesterol, so that the cholesterol content is 0·3–0·4 per cent. ; and the combined alcoholic solution is suitably diluted with saline. With this " antigen " a complement-fixation test is carried out in the usual way, and with the usual controls. The Wassermann reaction is, therefore, in no way specific in the bacteriological sense ; its basis is essentially empirical. It has been found in practice to be one of the most useful and reliable methods employed as laboratory aids to diagnosis ; but its diagnostic significance depends entirely on an observed correlation with clinical findings, for which there is, as yet, no satisfactory explanation. The methods of performing the test are legion (see Reports 1918*a*, 1924, 1929, 1934, Cumming *et al.* 1935, Vogelsang 1940) and many modifications have been suggested to increase its sensitivity. The principles are, however, in no way different from those outlined in Chapter 7, in connection with complement fixation in general.

Three reagents are concerned in the actual reaction—antigen, patient's serum, and complement. When these have been allowed to react for a suitable period—1 hour at 37° C., or overnight in the ice-box—sensitized red cells are added, and the mixtures are incubated for 1 hour at 37° C. to determine the presence or absence of hæmolysis, indicating he presence or absence of una bsorbed complement. To establish a positive reaction it must be shown (*a*) that the patient's serum alone absorbs no complement, or at most a small fraction of that present in the test mixture ; (*b*) that the same is true of the antigen ; and (*c*) that the mixture of serum and antigen absorbs an amount of complement greatly in excess of the sum of the small amounts absorbed by each of these reagents separately. Thus the essential tubes in carrying out a Wassermann reaction are (1) the antigen control, (2) the serum control, and (3) the test proper. The first control will serve for the whole series of tests carried out on any one day, the second must be put up for each serum tested. It is, however, obviously desirable to obtain a more accurate measure of the strength of the reaction than is possible by such a simple method as this ; and most of the methods in actual use are designed to yield a roughly quantitative result, which will enable the reactions to be graded into strongly positive, positive, weakly positive, doubtful, and negative. We may consider briefly the possible ways in which such results may be obtained, and the lines along which some approach to standardization may be sought.

There are three variables involved in the reaction—antigen, serum, and complement ; clearly, we may obtain quantitative results by holding any two of these constant, and varying the third. Varying the antigen introduces factors which need careful reconsideration in view of the recent advances in our knowledge of the importance of optimal relations in antigen-antibody reactions ; at the present time this method is seldom, if ever, adopted. With the amount of antigen held constant we may vary either the test

serum, or the complement. The latter method is very commonly employed, the serum-antigen mixtures being allowed to react in the presence of 3 and 5 M.H.D., or of 2, 4, 6 and 8 M.H.D. In either case the serum and antigen controls are put up with the smallest amount of complement employed in the test. In this way we grade the strength of a reacting serum in terms of the amount of complement which is fixed when a constant amount of serum (usually 0·5 ml. of a 1 : 5 dilution) is mixed with a constant amount of antigen (0·5 ml. of a suitable dilution), and the same volume of the suitably diluted guinea-pig's serum is added to the mixture.

An alternative method, advocated by several workers, is to hold antigen and complement constant, and vary the amount of patient's serum, testing it in progressive dilutions of, say, 1 : 2·5, 1 : 5, 1 : 10, 1 : 20, 1 : 40, though it is not usual to employ more than three dilutions. This method has the advantage of giving a direct measure of the concentration of the Wassermann-antibody in the serum under test. The serum control is, of course, put up with the largest amount of serum employed in the actual test.

In either case it is necessary to standardize the complement. For this purpose a preliminary titration is carried out, to determine the minimal hæmolytic dose. It is convenient to carry out this titration in duplicate. In the first series one volume of progressive dilutions of guinea-pig serum is added to two volumes of saline—0·5 ml. is usually taken as "one volume" throughout; in the second series the same dilutions of guinea-pig serum are added to one volume of saline and one volume of the antigen to be used in the test. After 1 hour's incubation at 37° C., or a longer time in the ice-chest, one volume of a 5 per cent. suspension of red cells and one volume of a hæmolytic serum, so diluted as to contain at least 5 M.H.D. of hæmolysin, are added to each tube; and both series are then incubated for 1 hour at 37° C. In this way we are able to determine the M.H.D. of complement (guinea-pig serum), before and after it has been allowed to react with the antigen. This obviates the necessity for any further antigen control, and enables us to detect any excessive anti-complementary action of the antigen, or any tendency of a particular specimen of guinea-pig's serum to react with the antigen alone. If such a test shows any marked difference in the M.H.D. in the two series, it may be taken that either the complement or the antigen is unsuitable, and must be replaced by a more satisfactory sample. In the test itself it is usual to employ 3 M.H.D. of complement, if this reagent is to be held constant. The use of dried complement, or of complement preserved in acid saline (Richardson 1941), adds considerably to the convenience of the test.

Precipitation Reactions, including the Kahn Test.—From our knowledge of the antigen-antibody reactions in general, we should expect that any reaction which gives complement fixation under a particular set of conditions will give visible precipitation if the conditions are properly adjusted. So far as the lipoid antigens and the serum antibodies involved in the Wassermann reaction are concerned, this is the case. The various methods for applying the precipitation test to the diagnosis of syphilis are scarcely less numerous than the modifications of the Wassermann reaction (Michaelis 1907, Meinicke 1907, Sachs and Georgi 1918, Vernes 1918, Dreyer and Ward 1921, Kahn 1922*a*, *b*, 1928, Report 1923, Report 1929, 1939, 1942, Hinton 1932, Kline 1932, Eagle 1932, Cumming *et al.* 1935, Rytz 1936, Laughlen 1935, 1938, Rappaport and Eichhorn 1943). For a general description of these tests, the monograph by Vogelsang (1940) may be consulted. A precipitation test possesses certain obvious advantages as compared with a complement-fixation reaction, for routine diagnostic purposes. It necessitates the use of two reagents only—serum and antigen. It is more easily standardized, and it is simpler to perform. The Kahn test, in particular, has been widely used during recent years.

The antigen employed in this test (Kahn 1928) is of the same general type as that used in the Wassermann test; but the preliminary extraction of the dried heart muscle, to remove the residual lipoid components, is carried out with ether instead of with acetone. The ether-extracted heart muscle is then extracted with alcohol, and cholesterol is added to the alcoholic extract. In preparing the antigen for use in the test, saline is added until an opalescent colloidal suspension is obtained, which disperses to give a clear solution on the addition of further saline, or serum. When the concentrations of the reagents are correctly adjusted, and flocculation is assisted by shaking, such an antigen, in the presence of a syphilitic serum, yields an almost immediate precipitate, while in the presence of a normal serum the solution remains clear and translucent. In the standard test three tubes are used. The amount of serum is kept constant (0·15 ml.), and the amount of antigen is varied (0·05 ml., 0·025 ml. and 0·0125 ml.). The tubes are shaken for 3 minutes, 1 ml. of saline is added to the first tube, 0·5 ml. to the second and third, and the results are read. In a weak reaction precipitation appears only in the third tube, with perhaps a trace of opalescence in the second; that is, with a serum which contains little "antibody," precipitation is inhibited by excess of antigen.

More recently, Kahn (1940*a*, *b*) has introduced a "verification test," in which the reaction is observed at both 1° C. and 37° C. It is based on the observation that reactions due to syphilitic antibody are generally stronger at 37° C. than at room temperature, and that those due to non-syphilitic antibody are generally stronger at 1° C. than at 37° C. The value of this test is still under discussion (see Chargin and Rein 1941).

The Interpretation of the Diagnostic Serum Reactions.—This is a problem that requires the closest co-operation between the clinician and the clinical pathologist, and its full discussion is beyond the scope of this book. It is considered at length in many of the reports and papers referred to above. For our present purpose we need consider only the results obtained in the most recent systematic surveys.

As a preliminary to any such discussion it is necessary to note the methods employed in recording and reporting results. The tests most frequently used do not permit a reading in terms of any titre, dilution or ratio, and their results cannot therefore be recorded numerically. The most common method of recording is to use an arbitrary combination of plus and minus signs. A strongly positive reaction may, for instance, be recorded as ++++, a less strong reaction as +++, a moderate reaction as ++, a positive but weak reaction as +, a doubtful reaction as +−, or −+, and a frankly negative reaction as −. Sometimes other conventions are used, the plus and minus signs being combined differently, or the strongest reaction being awarded only two, or three, plus signs. Such a notation has nothing to recommend it. The conventional signs used by one pathologist differ from those used by another, and confusion results. Alternatively, words may be used instead of signs; and we then have "strongly positive," "positive," "weakly positive," "doubtful" and "negative" reactions. This is a little better; but there is much to be said for the contention (see Cumming *et al.* 1935) that a division into "positive," "doubtful" and "negative" results gives the clinician all that he can gain, and simplifies the issue. Without some general agreement, these labels will of course be arbitrarily applied, and a proportion of the sera reported to be positive by one test, or one worker, will be returned as doubtful by another. The only way in which this difficulty could be reduced to a minimum would be to standardize the technique, and to issue standardized reagents from central laboratories (see Report 1934).

Taking things as they are, we may inquire what actually happens when sera from syphilitic and non-syphilitic cases are submitted to different kinds of tests. We may take first a trial that was carried out in Copenhagen in 1928, under the

auspices of the Health Organization of the League of Nations. Sera from several hundred persons clinically diagnosed as suffering from syphilis, and several hundred diagnosed as non-syphilitic, were submitted to various serological tests carried out by skilled pathologists from different countries (see Report 1929).

The significant figures taken from this report are tabulated, in a slightly modified form, in Table 178. The various modifications of the Wassermann reaction employed, or the various workers using this test, are designated as W.R.1, W.R.2, etc. The results obtained by the Kahn test are labelled Kahn 1 and Kahn 2. Other forms of precipitation tests are labelled P.1, P.2, etc. The results are recorded as " positive," " doubtful " or " negative." It will be seen that the reports on the clinically syphilitic cases vary rather widely, and that some of the workers recorded rather a high proportion of positive or doubtful reactions among the clinically non-syphilitic cases. Taking the results at their face value, and allowing for the

fact that many of the clinically syphilitic cases were clearly not in a stage in which they would give a positive serum reaction, WR.3 with 42·6 per cent. of negatives among the clinically syphilitic, and 97·2 per cent. among the non-syphilitic has given satisfactory results. Both series of Kahn tests do better than this, and so does P. 2.

The variability of the results with sera from clinically syphilitic patients, and the relatively high proportion of negative results, are not surprising; because all stages and types of syphilis were included, and it is well known that the proportion of positive reactions varies widely in different stages and types of the disease. Boas, for instance (see Reports 1918*b*, 1919), records 59 per cent. of positive results in primary syphilis, 90 per cent. in secondary syphilis, 84 per cent. in tertiary syphilis, 72 per cent. in tabes, and 99·3 per cent. in general paralysis of the insane. It is in the type of case that shows a relatively low proportion of positive reactions,

and a relatively high proportion of doubtful reactions, that most discrepancies will occur.

A report by the Public Health Service of the United States (see Cumming *et al.* 1935) gives valuable figures.

Table 179 has been constructed from the data contained in this report and records the percentage of positive results obtained by various tests, and by various workers, in the examination of sera from syphilitic patients in various stages of the disease, and from normal persons showing no evidence of syphilis. The notation used is the same as in Table 178; but it should be noted that Kahn 2 and Kahn 3 refer to modifications of the standard Kahn test, and that the W.R.1, P. 1, etc. of one table are not identical with the W.R. 1 and P. 1 of the other.

* See text.

It will be noted that the proportion of positive results is, on the average, far higher than in the Copenhagen trial; but this may well be due in large part to the nature of the cases examined. Most of the workers recorded 100 per cent. of positives in the untreated secondary cases; but the percentage of positives recorded in the untreated primary infections ranges from 53·7 per cent. to 82·9 per cent., and in the tertiary cases from 58·0 per cent. to 86·4 per cent. (For a further series of comparative trials, see Parran *et al.* 1937.)

More useful information is obtained by making a comparison, not between syphilitic and normal persons, but between persons suffering from syphilis, and persons suffering from some other disease. Very extensive studies have been made along these lines with results that may be summarized as follows. There is general agreement that yaws, which is closely related to syphilis in its ætiology, responds in much the same way to various serum tests. Cases of leprosy give a lower, but still relatively high, proportion of positive reactions. It has often been stated that patients suffering from malaria tend to give positive reactions; but here there has been a considerable conflict of evidence. The same is true of sleeping sickness. Some observers have recorded a small proportion of positive reactions in tuberculosis,

some in febrile conditions, and some in pregnancy. The trial carried out by the Public Health Service of the United States provides information on several of these points, and Table 180 has been constructed from the relevant data, including all the syphilitic cases, and the normal persons, from Table 179.

TABLE 180

RESULTS OF COMPARATIVE TRIALS OF DIFFERENT COMPLEMENT-FIXATION AND PRECIPITATION TESTS.

* See text.

It will be noted that the frequency of a positive reaction in leprosy is amply confirmed, that malaria yields an appreciable proportion of positive results, and tuberculosis far less, while the figures for febrile conditions and pregnancy differ but little from the normal. Another point will be noticed. On the whole, though there are exceptions, a test that tends to give a high proportion of positive results with sera from syphilitic patients, tends also to give a relatively high proportion of positive results with sera from those suffering with other diseases (see, for instance, W.R.3, Kahn 2, P.2 and P.5), while a test that gives a low proportion of positives in one case tends to do so in the other (see W.R.4 and P.6). Here, again, the standard Kahn test gives satisfactory results.

It is clear that there is not a great deal to choose between diagnosis by complement fixation and diagnosis by a precipitin reaction, so far as reliability is concerned. By either method there will be a certain range of variation in the results recorded by different workers, unless one standardized technique carried out with standardized reagents is to be enforced. In any case, the onus of interpreting the test must rest with the clinician, when he has made due allowance for the stage of the disease, if the case is one of syphilis, and for the possible or probable existence of one of the infections that may sometimes induce similar changes in the serum. For a discussion of the causes of discrepancies in the results of the Wassermann and Kahn tests, the reader is referred to an article by Berger and Sutherland (1944).

As a general working rule, and excluding cases of yaws and leprosy, it may be stated that, in a suspected case of primary syphilis, in the period between the first appearance of the chancre and the development of the secondary rash, a positive

reaction will confirm the diagnosis, but a negative reaction will by no means contradict it. The latter is particularly true during the first 2 or 3 weeks after the chancre appears. In a case which, on clinical grounds, is regarded as secondary syphilis, a negative reaction tells very strongly against the provisional diagnosis. In such cases the test should always be repeated; and, if the second test is also negative, the diagnosis should be very carefully reconsidered. A persistently negative reaction, lasting through this stage, may be taken as practically excluding syphilitic infection. In tertiary syphilis, with the exception of general paralysis, and perhaps of syphilitic aneurysm, a negative reaction cannot be regarded as excluding the diagnosis, though it may tell definitely against it.

The use of the Wassermann reaction in the control of treatment is too complex to be considered here. Broadly, it may be stated that, in a case which comes under treatment early, and which is efficiently treated, the Wassermann reaction becomes negative and remains so; while in a case which escapes treatment during the early stages, or which is inefficiently treated during this period, it is extremely difficult, if not impossible, to produce a permanently negative Wassermann reaction by treatment administered several years after infection has been contracted (Browning and Mackenzie 1924, Report 1926).

It may be added that the tests used in the examination of the blood serum may also be applied to the cerebrospinal fluid in suspected cases of neuro-syphilis; though certain of the precipitin tests give rather poor results when used for this purpose (see Cumming *et al.* 1935).

Such examinations should, of course, be controlled by examination of the fluid for cells, proteins, type of colloidal-gold curve and so on.

A diagnostic *agglutination test* has been described by Tani (1940), in which the patient's serum is mixed with a suspension of spirochætes prepared by the treatment of syphilitic rabbit's testicle with weak antiformin; but it is too early as yet to say whether it will prove of value in practice.

Prophylaxis and Treatment.

We do not propose to discuss the various hygienic methods that have been advocated for the prevention of syphilis.

Bacteriological methods of prophylaxis do not exist. Animal experiments indicate that it is difficult or impossible to protect animals by vaccination with dead spirochætes against subsequent infection with living organisms (Uhlenhuth and Mulzer 1913, Grossmann 1929). Immune bodies have been demonstrated in the blood of infected animals, but so far the transference of passive immunity has been unsuccessful. Metchnikoff and Roux (1904*a*) obtained some evidence that apes inoculated with a weakly virulent strain of syphilis were protected against subsequent inoculation with a fully virulent strain, but the results were not conclusive. Treatment with salvarsan is successful in curing the disease in the early stages, but once the secondary stage has passed, definitive cure appears to be impossible.

A new method of treatment is now on trial, namely, that of hyperpyrexia or pyrotherapy. *Trep. pallidum* is apparently more susceptible to heat than are the tissue cells, and evidence has been obtained that by raising the body temperature to 41·5°–42° C. it is possible in experimentally infected rabbits to destroy the spirochætes *in vivo* (see Carpenter, Boak, and Warren 1932). The hyperpyrexia may be produced either by simple heat, by short-wave radiation, or in certain other ways. It is too early yet to say what value the method is likely to have in practice, but promising results have been reported (see Simpson 1935). A single treatment cannot be relied upon to kill all

spirochætes, but the method may prove useful in conjunction with chemotherapy (Boak *et al.* 1942).

More recently the introduction of penicillin has led to revolutionary ideas on the treatment of syphilis. A single course of one week's treatment seems to be capable in suitable cases of bringing about complete disappearance of the lesions, but it would be premature at the moment to attempt to evaluate this mode of treatment in terms of permanent cure.

Rabbit Syphilis.

Rabbit syphilis is a naturally occurring venereal disease of rabbits due to the spirochæte *Treponema cuniculi.* The disease was first described by Ross (1912) and the spirochætes were first observed by Bayon (1913). The incidence of the disease in wild rabbits varies considerably; according to some authorities as many as 20–40 per cent. in this country are affected. In hutch rabbits the disease is less common; Adams, Cappell, and McCluskie (1928) noticed it in 14 out of 228 rabbits. The lesions consist of small scaly patches, often slightly eroded and covered with a brownish crust, situated on the genitals or in the perineal region. Sometimes the nostrils or eyelids are affected. The spirochætes are found in large numbers in scrapings from the lesions and in sections; they are confined apparently to the superficial layers. The disease can be reproduced in normal rabbits by inoculation of an infective tissue suspension on to the scarified skin of the genital region; transmission can also be effected by mating, but with less constancy. The incubation period is from 2 to 8 weeks; once established, infection persists for months. In males spontaneous cure usually occurs, but in females the disease is very chronic. Rabbits suffering from rabbit syphilis can be infected with human syphilitic material, indicating that the two diseases are not identical (Noguchi 1922). *Trep. cuniculi* is morphologically indistinguishable from *Trep. pallidum*, though Noguchi (1922) says it is perhaps a trifle thicker and longer than the average *pallidum.* Like *pallidum* it stains rose-red with Giemsa. The disease is readily cured by intravenous injection of salvarsan, or by local application of Unguentum hydrargyri. (For further information on the disease and the properties of the causative organism, see Bessemans 1928, and Bessemans and de Geest 1928.)

YAWS

Yaws is a contagious inoculable disease characterized by the appearance of papules, which generally develop into a fungating, encrusted, granulomatous eruption (Manson 1914). It is widely diffused throughout the tropics, and occurs in its typical form only amongst the dark-skinned races. The causative organism, *Treponema pertenue,* was discovered by Castellani in 1905. It is a spirochæte morphologically indistinguishable from *Trep. pallidum.* Yaws occurs particularly in childhood. The commonest site for the primary lesion is on the lower extremities. The secondary eruption usually appears 2–4 weeks later. The disease is not as a rule of venereal origin. Some observers believe that infection occurs through the skin and is carried by gnats. Patients with yaws give a positive Wassermann reaction. The disease is curable by salvarsan and is amenable to treatment with mercury and potassium iodide.

The main interest of yaws is its relationship to syphilis. Many experienced clinicians are of the opinion that yaws is syphilis modified by race and climate.

There is evidence that yaws protects against syphilis. Parham (1922), for example, never once observed syphilis in the Samoans, in spite of their close contact with Europeans; since nearly all Samoans are stated to have yaws in childhood, he argues that the disease must protect them from syphilis in adult life. Similarly Wilson and Mathis (1930), who in a period of 9 years in Haiti saw 45,000 cases of yaws and 300 cases of syphilis, only once met with an undoubted case of syphilis in a patient who had previously suffered from yaws. Further evidence is necessary, however, to determine the relationship between these two diseases.

CHAPTER 82

WEIL'S DISEASE AND OTHER LEPTOSPIRAL DISEASES: RAT-BITE FEVER

SINCE the discovery by Japanese workers in 1915 of *Leptospira icterohæmorrhagiæ* as the cause of Weil's disease, an increasing number of infections due to leptospiræ have been recognized in different parts of the world. Many of them differ in their clinical picture from Weil's disease, and have been given distinctive names, such as swamp fever, 7-day fever, autumn fever, and so on. As so often happens, the finding of new species similar to that responsible for a well-known disease has created difficulties in terminology. Are we to use the name by which the disease has been described; or is it better to select an all-embracing term such as Leptospirosis, qualifying this, perhaps, as Walch-Sorgdrager (1939) suggests, by adding the specific name of the causative organism, so that we have Leptospirosis grippotyphosa, Leptospirosis hebdomadis, Leptospirosis autumnalis? Our personal preference is, wherever possible, to retain the original name of the disease, even though it means extending the clinical picture beyond that originally described. When the same name has been given to a disease caused by two different organisms, as for example the autumn fever of Japan and the autumn fever of Australia, it may be wise for the sake of clarity to mention the name of the causative leptospira, e.g., autumn fever of the *autumnalis* or the *pomona* type. If we give way to the modern tendency of calling every disease after the generic name of the causative organism, not only shall we have an increase in the already too abundant and monotonous "*oses*" diseases, such as staphylococcosis, streptococcosis, rickettsiosis and so on, but we shall have to abandon the names of age-long familiarity, such as scarlet fever, diphtheria, dysentery, plague, influenza, and typhus fever.

WEIL'S DISEASE

SYNONYM: *Spirochætosis icterohæmorrhagica*

Weil's disease is a fairly widespread and not uncommon disease, which frequently assumes prominence in war-time. During the American War of Secession, 1861–65, over 70,000 men contracted infectious jaundice, that is between 2·0 and 2·5 per cent. of the total strength (Uhlenhuth and Fromme 1916). In the first world war it was common on the Western front, affecting both German and Allied troops (Uhlenhuth and Fromme 1916, Stokes *et al.* 1917, Martin and Pettit 1919). The disease was reported in Scotland in 1923 amongst the coal-miners of the East Lothian district. It appears to be fairly common in South America. It is frequently met with in Sumatra (Sardjito and Zuelzer 1929), and has been observed in the Andaman Islands (Brown 1928, Taylor and Goyle 1931). It is very common in

Japan, where in 1933 there were as many as 1,636 cases. The United States seems to suffer but little. In Europe, Holland and France appear to have the highest incidence rate, but statistics of the real prevalence of the disease are unobtainable (see Report 1934). In Great Britain it is endemic in sewer workers (Fairley 1934, Alston and Brown 1935, Stuart 1939) and in those engaged in washing fish (Davidson *et al.* 1934, Davidson and Smith 1936, Smith and Davidson 1936).

The incubation period of the disease is 5 to 7 days as a rule, rarely as long as 13 days (Inada 1917). In the first or febrile stage, which lasts for 6 or 7 days, there is high fever, conjunctival congestion, muscular pains, and albuminuria. In the second or icteric stage, which lasts from the 7th to the 13th day, jaundice appears, there is a tendency to hæmorrhage, and death may occur. The third stage, or stage of convalescence, is marked by the gradual subsidence of the jaundice and other symptoms; it may be interrupted, however, by a secondary fever (Inada 1917). The mortality of the disease varies in different epidemics; in Japan it varies from 4·6 to 32 per cent. (Inada *et al.* 1916, Report 1934); on the western front during the war of 1914–18 it was under 6 per cent. amongst the British, and 13 per cent. amongst the German troops (Stokes *et al.* 1917, Uhlenhuth and Fromme 1918); in the Scottish outbreak it was about 25 per cent. (Buchanan 1927).

The disease varies considerably in its symptomatology. In something like 60 per cent. of cases no jaundice occurs (Schüffner 1934); these cases are never fatal. Infection may take the form of a serous meningitis, unaccompanied by the usual symptoms of Weil's disease (for references see Walch-Sorgdrager 1939); this form is likewise seldom fatal.

The disease is due to infection with a spirochæte that was first described in 1915 by Inada and his colleagues in Japan (Inada *et al.* 1916). The usual name for this organism is *Leptospira icterohæmorrhagiæ*, but in Germany it is generally referred to as *Spirochæta icterogenes* (see Chapter 38). A few cases appear to be caused by *Lepto. canicola*—a closely allied species that is normally a pathogenic parasite of the dog (Schüffner 1934).

In man the spirochætes are widely distributed in the body during the 1st week of the disease, and can generally be demonstrated in the blood by guinea-pig injection, and occasionally by microscopical examination. After the 7th to 9th day they leave the blood and appear in the urine, at first in very small numbers, but gradually increasing till during the 3rd and 4th weeks they can be found microscopically by dark-ground illumination in the majority of cases. They persist in the urine for a variable time, but can rarely be found after the end of the 5th week. In patients dying during the febrile stage of the disease spirochætes can be demonstrated microscopically in the kidney, liver, adrenals, spleen, testicle, lymphatic glands, voluntary and cardiac muscle, and arterial walls; less frequently in the lung, pancreas, intestine, nervous system, and skin (Inada *et al.* 1916). If death occurs during the 2nd week or later, the chief organ in which spirochætes are found is the kidney; in the other organs they are less numerous or absent.

Occupational Incidence.—Weil's disease occurs chiefly in damp, badly drained, rat-infested situations. Thus in Japan it was noticed that the disease occurred in coal mines; that only the miners who worked in a particular section of the mines were affected; that this section was under water; and that when the water was pumped out, no more cases occurred (Inada *et al.* 1916). Later, it was noticed that cases never occurred in coal mines when the soil was acid; on the other hand

they were numerous in coal mines on an alkaline soil (Ido *et al.* 1917*a*). Experiments have shown, in this connection, that the organisms are rapidly killed by a weakly acid solution. On the western front in 1914–18 Stokes (Stokes *et al.* 1917) observed that the cases occurred mainly amongst the troops in the trenches; at the base they were very uncommon. Most of the cases, moreover, occurred in small sections of trench that were particularly wet and badly drained. Rats taken from one of these sections were found to contain pathogenic leptospiræ in the kidneys. Similar observations were made in the German Army (Uhlenhuth and Zuelzer 1921). Again in Scotland, Buchanan (1927) observed the disease amongst coal miners in the East Lothian district; pathogenic leptospiræ were found in the roof slime of a mine, and similar leptospiræ, the pathogenicity of which was not determined, were frequent in pit and surface waters; infected rats were likewise found in the mines. In the Andamans, cases are practically confined to adult males engaged in outdoor occupations that necessitate working in water and mud for prolonged periods, such as in the rice fields (Taylor and Goyle 1931). In Holland the majority of the cases are contributed by swimmers, bargemen, fishermen, slaughter-house workers, and persons who by accident or with suicidal intent fall into canals, and are nearly drowned after swallowing large quantities of water (Schüffner 1930, 1934). In this country, as has already been stated, sewer workers and those engaged in washing fish are specially liable to the disease.

One very instructive *water-borne outbreak* is on record (Jorge 1932). It occurred in the north-east quarter of Lisbon in 1931, and involved at least 126 persons in the space of a month. Infection was traced to a particular fountain, the water of which during its passage underground in an open conduit had apparently been contaminated by rats from a neighbouring sewer. The case mortality of this epidemic was 24·6 per cent.

Mode of Transmission.—The mode of transmission of Weil's disease is not known with certainty, but there is strong reason to believe that infection takes place directly or indirectly by contamination of the abraded skin or of a mucous membrane, such as that of the eye, nose, or mouth, with rats' urine. The occupational incidence, which has just been referred to, affords striking evidence in favour of this conclusion, since contact with presumably contaminated water or sewage seems to be common to all types of persons attacked. Further evidence is provided by consideration of the frequency with which leptospiræ are found in apparently normal rats. Occasional cases follow an actual rat bite (see Alston and Brown 1937).

Infection of Rats.—It has been established by numerous workers that the rat—particularly *Rattus norvegicus*—is a very frequent carrier of pathogenic leptospiræ.

In Japan 40·2 per cent. of 149 rats of this species were found infected (Ido *et al.* 1917*a*); in England 30 per cent. of 100 wild rats (Balfour 1922, Stevenson 1922); in Scotland 36·7 per cent. of 166 wild rats (Buchanan 1927) and 27·3 per cent. of 117 wild rats (Smith 1938); in Berlin 10 per cent. of rats (Uhlenhuth and Zuelzer 1921); in Toronto 37 per cent. (Cameron and Irwin 1929); in Freiburg 44 per cent. (Zimmermann 1930); in Moscow 12 per cent. (Ssinjuschina 1929); and in Kiew 31 per cent. (Basilewsky 1933). In Rotterdam, where cases of Weil's disease are fairly common, from 7 to 40 per cent. of all rats examined have proved to be infected (Schüffner 1934). The frequency of infection depends largely on the age of the rat. Young rats are seldom infected, while over 50 per cent. of adult rats may harbour the spirochætes. The black rat rarely acts as a carrier. Field-mice are not uncommonly infected (Ido *et al.* 1917*a*, Buchanan 1927).

The spirochætes are found in the kidney and the urine, not in the blood or liver. Intraperitoneal injection of rat's urine, even in small amounts, 0·1–0·2 ml., into guinea-pigs may give rise to fatal hæmorrhagic jaundice. Not all specimens of rat's urine in which leptospiræ are visible microscopically prove infective ; this is probably dependent on the acidity of the rat's urine, which rapidly proves fatal to the organisms. The same applies to the effect of human urine ; only in one-third of cases of Weil's disease does the urine prove to be infective. Uhlenhuth and Zuelzer (1921) found that fresh human or rat's urine rapidly killed the spirochætes ; but if the urine was neutralized, the organisms remained virulent for 2 days.

Leptospiræ in Water.—In view of the frequency of infection of rats' urine, it should be possible to demonstrate the presence of *Lepto. icterohæmorrhagiæ* in contaminated water.

Spirochætes morphologically identical with *Leptospira icterohæmorrhagiæ* are widespread in water. They were first observed by Wolbach and Binger in 1914, and have since been found by numerous workers in different parts of the world. In this country and in America they are known as *Leptospira biflexa* and in Germany as *Spirochæta pseudoicterogenes* (see Chapter 38). As pointed out by Zuelzer (1928) they are generally found attached to other spirochætes and protozoa. They are especially prevalent in the slime of ponds, lakes, and rivers, in the slime that collects on the ends of water taps and pipes, and in the roof slime of mines. They are very susceptible to acid and are therefore confined to waters with a pH of over 6·8. Thus they are abundant along the east coast of Sumatra where the water is alkaline and practically absent from Java where the water is acid (Sardjito and Zuelzer 1929). They are also susceptible to salt, and are said to perish in 3 days in alkaline water containing 0·17 per cent., and in a few hours in water containing 1·7 per cent., of chlorine as chloride (Schüffner 1934).

These organisms have occasioned much discussion. For some time opinion was influenced by the experiments of Baermann and Zuelzer (1927, 1928). These workers brought evidence to suggest that, though on first isolation water leptospiræ were avirulent, by passage through guinea-pigs, or occasionally through human beings, they could be so raised in virulence as to give rise in the guinea-pig to typical hæmorrhagic jaundice. In fact Baermann and Zuelzer regarded *Lepto. biflexa* merely as an avirulent form of *Lepto. icterohæmorrhagiæ*. Extensive observations by various workers have failed to confirm these findings. Possibly Baermann and Zuelzer were working with a strain of *Lepto. icterohæmorrhagiæ* that had become avirulent by residence under saprophytic conditions, or they may have isolated from one of their guinea-pigs a naturally infective strain entirely different from their passage strain. Except in special conditions, where the locality is heavily rat-infested, it is uncommon to isolate a pathogenic leptospiral strain from water. Since *Lepto. biflexa* is widely distributed over the globe, while cases of Weil's disease are topographically and occupationally circumscribed, it is difficult to avoid the conclusion that *Lepto. biflexa* has no ætiological relationship to the disease. Most of the evidence suggests that water becomes contaminated with *Lepto. icterohæmorrhagiæ* from rats' urine, and that even in favourable circumstances the organisms die out fairly rapidly. For this reason infection of human beings is unlikely except from water exposed to frequent and heavy contamination.

Summarizing, it may be said that the evidence points strongly in favour of infection occurring through contact, often close and prolonged, with water or sewage recently contaminated with the urine of rats. A few cases of laboratory infection by contamination of the conjunctiva or the abraded skin with infective guinea-pig material have been recorded (Uhlenhuth and Fromme 1916, Uhlenhuth and Zimmermann 1933).

Diagnosis.—According to Schüffner (1934), 60 per cent. of patients with Weil's disease show no jaundice. The true nature of the illness in these cases is suggested by the severe muscular pains at the onset, the heavily coated tongue, the albuminuria, the meningeal symptoms, the increase in the proportion of immature polymorphonuclear leucocytes, and probably most striking of all the flushed conjunctivæ due to dilatation of the episcleral capillaries. Cases without jaundice are not fatal.

The diagnosis has to be made finally by the bacteriologist. Several methods are available. In general the aim is to demonstrate the organisms in the blood during the 1st week of the disease and in the urine during the subsequent weeks, and to confirm the diagnosis by serological examination. Though leptospiræ can almost invariably be found by dark-ground illumination in the freshly drawn blood of infected guinea-pigs, they are rarely found by this method in human cases. Cultivation of the blood is much more successful, and in the hands of certain workers, such as Taylor and Goyle (1931), has yielded a high proportion of positive results; over 80 per cent. of positive cultures were obtained when the blood was withdrawn on the 4th or 5th day of the disease. Fletcher's medium (see Chapter 38) is recommended. Alternatively, 2–3 ml. of the blood may be inoculated intracardially or intraperitoneally into young guinea-pigs (see p. 922); the success of this method seems to depend on the virulence of the infecting strain. After the 1st week or 10 days of the disease, the organisms usually disappear from the blood and must be sought for in the urine. This should be examined by dark-ground illumination and by guinea-pig inoculation. The microscopical diagnosis is not always easy or reliable, since leptospiræ in acid urine are often atypical in shape and may be granular and degenerated (Buchanan 1927); for this reason it is advisable to give the patient potassium citrate to render the urine alkaline.

For ease and rapidity of diagnosis more and more attention is being paid to serological methods of examination. Agglutinins, lysins, and complement-fixing bodies appear about the end of the 1st week of the disease and increase to reach their maximum after 4–7 weeks (Kisker 1935, Wolff 1936).

Agglutination may be carried out on slides incubated at 32° C. for 3 hours and observed under dark-ground illumination, using a low-power objective and a compensating ocular. If living organisms are used, agglutination is seen to occur in the lower dilutions and lysis in the higher. With formolized and phenolized suspensions agglutination alone is seen. Two or three different strains should be used, including one of *Lepto. canicola*. In most laboratories now the microscopic slide method has given way to the macroscopic tube method of agglutination. At first, living suspensions were used (Smith and Tulloch 1937), but these were replaced by suspensions killed with formalin. A simple and reliable technique has been described by Gardner (1943), who grows the organisms for 3 to 4 days at 30° C. in a 12 per cent. rabbit serum water medium, adds 0·25 per cent. formalin, filters through cotton-wool, makes up dilutions of serum from 1/25 to at least 1/1,000, and incubates the mixture for 24 hours at 37° C

By the end of the 1st week of the disease the titre should be at least 1/20; during the 2nd week it rises, and often passes the 1/1,000 level; sometimes, at a later stage of the disease, it may reach even 1/50,000. Reactions at 1/25 or even 1/100 cannot be taken as diagnostic, though complete flocculation at the latter level is very suspicious. Patients showing less than 1/100 at a first test should be re-examined after five days or so to establish a rise of titre. The interpretation of the result must depend not only on the titre, but on the clinical findings,

the occupation of the patient, and the frequency of latent infections in the locality. Agglutinins persist for a long time, and a retrospective diagnosis may be made even years after the attack (see Schüffner 1930, 1932, 1934, Gaehtgens 1933, Bijl and Korthof 1930, Davidson *et al.* 1934, Packchanian and Tom 1943). The *adhesion phenomenon* (see p. 912) may be used instead of direct agglutination (Brown 1935). Agglutinins are often present in the urine in titres up to 1/250 (van der Hoeden 1935). The complement-fixation test has been reported upon favourably by Pot and Dornickx (1936).

Spirochætocidal antibodies may be tested for by mixing 1–2 ml. of the patient's serum with several lethal doses of the organism, allowing the mixture to stand at room temperature for 30 minutes, and then injecting it into guinea-pigs. If protective bodies are present the animals will survive, while control animals will die of spirochætal infection.

The occurrence of a polymorphonuclear leucocytosis in Weil's disease is said to be of value in the differential diagnosis from epidemic jaundice, in which a lymphocytosis is usually observed (see Murgatroyd 1943).

The demonstration of infection in *rats* may be accomplished by dark-ground examination and cultivation of the kidney and urine, by microscopical examination of sections of kidney stained with Levaditi, by inoculation of mice or guinea-pigs with ground-up kidney tissue; or indirectly by examination of the blood serum, or less successfully the urine (see van der Hoeden 1936), for antibodies. Agglutinins and lysins are often present in the serum in a titre of 1/400–1/3,000 (see Cameron and Irwin 1929, Zimmermann 1930). Larson (1943) obtained the highest proportion of positive results by examination of the blood serum, taking a titre of 1/100 or over as diagnostic; examination of stained sections of kidney came next, followed by dark-ground examination of the kidney. In examining rats for leptospiral infection, it is important that the animals should be freshly killed, since the spirochætes disappear rapidly after death (Smith 1938). For demonstrating the presence of *Lepto. icterohæmorrhagiæ* in *water*, the method described by Appelman and van Thiel (1935) of scarifying the shaved abdominal skin of guinea-pigs, and immersing them in the water for an hour, seems to hold out most prospect of success.

Prophylaxis and Treatment.

The prevention of Weil's disease would seem to consist in the drainage of infected areas and the suppression or exclusion of rats.

Prophylactic vaccination of workers who are specially exposed to risk of infection has been tried on a considerable scale in Japan with very promising results. The figures of Wani (1933), in particular, are impressive. He used a phenolized vaccine and gave two doses. The morbidity rate in the vaccinated subjects was only about a quarter of that in the control population. Little experience has been gained of vaccination in Europe. The few observations made by Smith (1937) in Aberdeen were disappointing, but more favourable results have been reported from Amsterdam (see Walch-Sorgdrager 1939).

Treatment by salvarsan is unsatisfactory; Weil's disease is in fact the only spirochætal infection that does not yield to arsenic. The most promising line of treatment is by immune horse serum; according to Martin and Pettit (1919), 60 ml. of serum should be injected subcutaneously on the 1st day, and 20–40 ml. on each of the next 2 or 3 days. In severe cases it should be given intravenously. According to Walch-Sorgdrager (1939), who reviews the effect of serotherapy,

there is insufficient evidence as yet to prove conclusively that the serum exerts a specific action upon the infecting organism, but there is little doubt that it has a beneficial effect when administered within four days of the onset of the disease. There is some evidence that the case mortality may be lowered (see Inada 1923). Experimental observations on the guinea-pig suggest that penicillin may be of value in treatment (Heilman and Herrell 1944*a*). (For much useful information on Weil's disease, the reader is referred to the monograph by Taylor and Goyle 1931, to papers by Alston and Brown 1937 and Walch-Sorgdrager 1939, and to the review by Ashe, Pratt-Thomas and Kumpe 1941).

Other Leptospiral Infections of Human Beings

Throughout the world there are a number of diseases simulating to a greater or lesser extent Weil's disease, but caused by leptospiræ that differ from *Lepto. icterohæmorrhagiæ* in their antigenic or pathogenic properties, and sometimes in their natural animal reservoir (see Chapter 38). No satisfactory classification of these diseases is yet possible and, as has already been pointed out, their nomenclature is in a state of confusion. We propose to group them tentatively according to our present inadequate knowledge of their clinical and epidemiological features, and to some extent according to the apparent affinities of their causative organisms (see Table 181). (For references to these diseases, see Walch-Sorgdrager 1939.)

Group A. Hasamiyami, and some diseases of the Dutch East Indies and the Andaman Islands resembling Weil's disease.

Hasamiyami is a disease found mainly among the peasantry of Nagasaki (see Kotorii 1935, Kaneko, Kotorii and Aoki 1935). Jaundice is fairly common, glandular swelling occasional, and clouding of the vitreous humour almost constant. The mortality is not more than about 2 per cent. The causative agent is *Lepto. autumnalis*, which appears to be identical with *Lepto. akiyami A.* The natural reservoir of infection is a field-mouse, *Apodemus speciosus.*

Cases of leptospiral infection simulating Weil's disease have been described among plantation workers in Sumatra caused by *Lepto. rachmat*, and among convicts and soldiers in the Andaman Islands, due to *Lepto. andaman A.* The animal reservoir of these two organisms is unknown, but it may well prove to be field-rats or mice.

An endemic infection among plantation workers in Sumatra due to *Lepto. salinem*, and sporadic infections among men and women in Batavia, Borneo, Macassar, and other parts of the Dutch East Indies, due to *Lepto. bataviæ*—sometimes known as the Swart van Tienen type—may be included in this group. *Lepto. salinem* is carried by *Rattus brevicaudatus*, and *Lepto. bataviæ* by *Rattus norvegicus.*

These diseases all resemble Weil's disease in some respects; all may give rise to jaundice and hæmorrhages; all may prove fatal, though as a rule the case mortality is low; and all are caused by organisms that are moderately virulent for the guinea-pig. There is some reason to believe that the agglutinins, instead of being demonstrable in the blood serum of patients for years after the attack—as in Weil's disease—may disappear completely within a year (Wolff 1936).

Group B. Nanukayami, Akiyami, Coastal fever of Queensland.

Nanukayami, sometimes known as *sakushu* fever or the *7-day fever of Japan*, is an autumnal disease occurring in many rural districts of Japan. Jaundice is slight or absent, and the disease is never fatal. We owe our knowledge of its

TABLE 181

SUMMARY OF THE KNOWN FORMS OF HUMAN LEPTOSPIRAL INFECTIONS (Modified from Walch-Sorgdrager, 1939).

Disease.	Clinical Symptoms.	Epidemiological Features.	Causative Organism.	Animal Inoculation.	Carrier.
Weil's	Jaundice frequent. Mortality variable, but often high.	Affects persons brought into contact with water contaminated by rats' urine, endemic in sewer and mine workers. Males much more often affected than females.	*L. icterohæmorrhagiæ.*	Virulent for guinea-pigs, producing jaundice.	Rats, *Rattus norvegicus* and *R. alexandrinus.*
Hasamiyami	Jaundice fairly frequent. Seldom fatal.	Endemic among peasants in Nagasaki during autumn. Men more often than women.	*L. autumnalis* (apparently identical with *L. akiyami A*).	Moderately virulent for guinea-pigs, often producing jaundice.	Field-mice, *Apodemus speciosus.*
Simulating Weil's disease	Jaundice fairly frequent. Mortality low. Vitreous opacities common	Endemic in Dutch East Indies. Mainly among plantation workers.	*L rachmat.*	Virulent for guinea-pigs, usually producing jaundice.	?
Simulating Weil's disease	Jaundice fairly frequent. Mortality low to moderate.	Among soldiers and convicts working in mud in the Andaman Islands. Chiefly in autumn.	*L. andaman A.*	Moderately virulent for guinea-pigs	?
Simulating Weil's disease	Jaundice not infrequent. Mortality low to moderate.	Endemic in Dutch East Indies, often in workers on plantations. Men and women affected.	*L satanem* and *L. bataviæ.*	Moderately virulent for guinea-pigs, often producing jaundice.	Rats, *R. brevicaudatus; R. norvegicus.*
Nanukayami or 7-day fever; Akiyami or Autumn fever of Japan.	Jaundice rare. Swelling of lymph glands. Not fatal.	Sometimes in epidemic form in rural areas of Japan during autumn.	*L. hebdomadis* (apparently identical with *L. akiyami B*).	Virulence for guinea-pigs slight or absent.	Voles, *Microtus montebelloi.*
Cane or Coastal fever of Queensland.	Jaundice rare. Glands often enlarged. Severe, but seldom fatal.	Cane-field workers in Queensland. Mainly men.	*L. australis A* and *B.*	Moderately virulent for guinea-pigs.	Cane-field rats, *R. culmorum.*
Weil-like disease . .	Jaundice uncommon.	Rural workers in Denmark.	*L. sejroe.*	Virulence for guinea-pigs very low.	Field-mice, *Mus spretegus.*
Swamp fever . . . Mud fever	Jaundice rare. Not fatal.	Epidemic and endemic among people working on swampy ground; common in late summer in Russia, Germany, Italy, Andaman Islands, etc.	*L. grippo-typhosa* (apparently identical with *L andaman B*).	Virulence for guinea-pigs very low or absent.	? Voles, *Microtus arvalis*
Pomona fever, or 7-day fever of Queensland.	Jaundice rare. Not fatal.	Among dairy workers in Queensland during summer and early autumn.	*L. pomona*	Virulence for guinea-pigs very low.	Endemic infection of pigs and cattle.
7-day fever of Queensland.	Jaundice rare. Not fatal.	Among workers with farm animals.	*L. mitis*	Virulence for guinea-pigs moderate	Endemic infection of pigs and cattle.
Weil's	Jaundice rare. Not fatal. May be meningeal symptoms	Infection from dogs.	*L. canicola.*	Virulence for guinea-pigs very low.	Dogs

bacteriology to the Japanese workers, Ido, Ito and Wani (1918, 1919). Th causative organism is *Lepto. hebdomadis*, and the natural reservoir of infectio the vole, *Microtus montebelloi*.

Akiyami, or the Autumn fever of Japan, is a disease similar to nanukayami Indeed one type of leptospira isolated from some of the cases, known as the *Lepto akiyami B* type, appears to be identical with *Lepto. hebdomadis* (Stéfanopoul and Hosoya 1928). The *A* type is apparently identical with *Lepto. autumnalis*—already mentioned as the cause of hasamiyami.

In northern Queensland there is a group of coastal fevers that are gradually being differentiated. From one group, common among workers in the sugar-cane fields, two types of leptospira have been isolated—*Lepto. australis A* and *B* (Lumley 1937). The *A* species is clearly distinct; the *B* species is closely related to *Lepto. salinem* (Walch-Sorgdrager 1939). The animal reservoir appears to be a field-rat —*Rattus culmorum*.

Another leptospiral infection that may be included in this group is a mild disease recorded in Denmark by Petersen and Christensen (1939) due to an organism named *Lepto. sejroe*. Country workers are mainly affected, and the natural animal reservoir appears to be a field-mouse—*Mus spicilegus*.

The diseases included in this group tend to be milder than those classified under Group A. They occur mainly among rural workers. The usual clinical picture is a febrile disease lasting about a week, seldom accompanied by jaundice, and rarely proving fatal. The causative leptospiræ have, as a rule, only a low degree of virulence for the guinea-pig, and the natural animal reservoirs are field-mice.

GROUP C. **Swamp Fever.**

This disease, which is also called by such names as Mud fever, Slime fever, Harvest fever, Field fever, or the German Schlammfieber, is widespread in eastern Europe. It has been studied particularly in Germany (see Kathe 1928, 1941, Korthof 1932, Rimpau 1937, Wolter 1939), and in Russia (Tarassoff 1935). It has been reported in the Andaman Islands, the *B* type of leptospira there being apparently identical with the causative organism of swamp fever, *Lepto. grippotyphosa*. Whether the disease reported among the rice-field workers of northern Italy by Mino (1937, 1938, 1939, 1942) and Babudieri (1939) is the same disease as swamp fever is difficult to say, but so far as can be ascertained more than one type of leptospira seems to be responsible. Swamp fever may occur in epidemics of considerable magnitude. Field workers in swampy districts are attacked, particularly during the hay harvest. Young adult males constitute a considerable proportion of the cases, presumably because of their greater exposure to infection from contaminated water. Clinically the onset is sudden with rigors or chills, headache, pains in the back and limbs, often severe cramps in the calves, and sometimes nausea, vomiting, and diarrhœa. In a minority of the cases a macular eruption appears on the body and face on the 3rd or 4th day. Jaundice is uncommon. The disease lasts for 5–7 days, the temperature falling by lysis. There is sometimes a short relapse 1 or 2 days later. The case mortality is about 0·4 per cent. (Korthof 1932). The disease can be reproduced in human subjects by inoculation with pure cultures of the infecting organism. Leptospiræ can be demonstrated in the blood during the first 2 days of the disease. In practice bacteriological diagnosis is best made by examination of the blood serum for agglutinins, which often reach a titre of over 1/1000 by the 2nd week. The

virulence of *Lepto. grippo-typhosa* for guinea-pigs is very low or absent. The animal reservoir is not known with certainty, but the vole (*Microtus arvalis*) is suspected (Schüffner and Bohlander 1942).

The disease in man is not to be confused with the *swamp fever* or *infectious anæmia of horses*, which is apparently due to a filtrable virus (Stein 1935) (see p. 1966).

It will be realized that the diseases in this group are often characterized by gastro-intestinal symptoms; jaundice is uncommon, and death rarely occurs. The causative organism is almost non-virulent for guinea-pigs.

GROUP D. **Seven-day fever of Queensland, and other diseases.**

Clayton and Derrick (1937) described a 7-day fever in Queensland due to an organism named *Lepto. pomona*. Later Johnson (1942) described a very similar disease—also in Queensland—due to a different organism, *Lepto. mitis*. Both these diseases occur mainly in farmers and workers who are in contact with farm animals. The disease is mild, jaundice is rare, and death does not occur. Whether there is a rodent carrier is still unknown, but both types of leptospira have been found to be endemic in pigs and cattle.

Another disease that may be considered here is a febrile infection due to *Lepto. canicola*, an organism whose natural carrier is the dog. The disease caused by this organism has been met with sporadically in different parts of the world. It is usually mild, though sometimes chronic, is unaccompanied by jaundice, and is not fatal. Meningeal symptoms may occur.

The diseases classified in this group are similar in their mildness to those in Groups B and C. Infection, however, seems to be contracted not from rodents, but from the larger domestic animals. The causative organisms have, as a rule, only a very low degree of virulence for guinea-pigs.

SPIROCHÆTAL JAUNDICE IN ANIMALS

We have already mentioned that about 20–30 per cent. or so of wild rats are infected with *Lepto. icterohæmorrhagiæ*. The organism apparently gives rise, however, to little systemic disturbance in these animals, and rarely causes jaundice.

A disease, similar to Weil's disease and accompanied by jaundice, is not infrequent in **dogs** (see Okell *et al.* 1925). It appears to be caused, as a rule, by *Lepto. icterohæmorrhagiæ*. More frequently, however, leptospiral infection in dogs is due to *Lepto. canicola*, and takes the form, not of jaundice, but of uræmia (Stuttgart dog plague, canine typhus of Lukes). The disease caused by *Lepto. icterohæmorrhagiæ* affects dogs up to 3 years of age, runs an acute course, is accompanied by jaundice, and has a case mortality of about 50 per cent. The disease caused by *Lepto. canicola* tends to attack slightly older dogs, runs a more chronic course, is characterized by an azotæmic-uræmic syndrome due to affection of the kidneys, is seldom accompanied by jaundice, and has a case mortality varying from 40 to 80 per cent. (see Dhont *et al.* 1934, Schüffner *et al.* 1935, Klarenbeek 1938, Niemand 1940). There is, however, no sharp line of demarcation between the two diseases. Infections with *Lepto. canicola* appear to be twice as frequent as those due to *Lepto. icterohæmorrhagiæ* (Klarenbeek 1938). The disease due to *Lepto. canicola* is much commoner in dogs than in bitches, partly because this organism is excreted in the urine more often than *Lepto. icterohæmorrhagiæ*, and partly because of the habit so common in dogs of sniffing the urine or external

genitalia of other dogs (Walch-Sorgdrager and Schüffner 1938). Dogs may act as healthy carriers of leptospiræ; Kouwenaar and Wolff (1930) in Sumatra found 5·7 per cent. of street dogs to be infected. Such dogs constitute a source of danger for man. Bacteriological diagnosis follows the general lines already laid down for the human disease; demonstration of agglutinins and lysins in the dog's serum is a rapid and convenient method (van der Hoeden 1935).

Leptospiral infections have been encountered in foxes (Dunkin and Laidlaw 1924–25), in mice (Bessemans and Thiry 1929), in cats (Esseveld and Collier 1938), and in certain other animals.

RAT-BITE FEVER

As has already been pointed out (p. 1276), there appear to be two distinct diseases known as rat-bite fever, one due to *Spirillum minus*, the other to an organism generally referred to as *Streptothrix moniliformis*, but better called *Actinomyces muris*. We shall consider here only the spirillar type of infection.

Rat-bite fever, or *Sodoku* as it is called in Japan, is a disease that occasionally supervenes in man on the bite of a rat, or occasionally some other animal such as a cat (Mollaret and Bonnefoi 1938, Yamamoto 1939). The incubation period is generally 7 to 21 days, but it may extend to weeks or even months. The disease is ushered in by a sharp febrile paroxysm accompanied by swelling of the lymph glands and dark-red eruptions on the skin. Redness and swelling are noticed at the site of the wound, which during the incubation period has generally healed satisfactorily. There are often pains in the limbs on the affected side. After 3 or 4 days the attack comes to an end, but is succeeded by another in a few days. These febrile paroxysms with intermittent afebrile periods may be repeated for months, or even years. The mortality of the disease varies from about 2 to 10 per cent.

The causative organism of the disease is a *Spirillum*, which was described in 1916 by Futaki and his co-workers (Futaki *et al.* 1916) in Japan (see p. 1838). The organism has been found in cases of rat-bite fever in this country (Robertson 1924), in Italy, Turkey, India, Dutch East Indies, and the United States (Shattock and Theiler 1924, Brown and Nunemaker 1942, Beeson 1943). (For a review of the literature see Robertson 1924, Theiler 1926, McDermott 1927–28, Brown and Nunemaker 1942.) The disease has been reproduced experimentally in human beings by inoculation with infected guinea-pig blood (see Hershfield *et al.* 1929). The clinical differentiation of the disease caused by *Sp. minus* from that caused by *Actino. muris* has been studied by Allbritten, Sheely and Jeffers (1940) and Brown and Nunemaker (1942), and is referred to on p. 1278. In tsutsugamushi fever (see p. 1849), with which rat-bite fever may be confused, the local ulcer is said to be larger, more irregular in outline, and painful, and the elements of the rash on the trunk are of greater size (Lewthwaite 1940).

In the human patient the organism is present in the swollen local lesion, the focal lymph glands, and the blood, but it is very difficult to demonstrate except by animal inoculation; at autopsy it can be found also in the kidneys (Kaneko and Okuda 1917). Microscopical examination of the blood is usually negative. The Wassermann reaction is said to be positive in about half the cases (Brown and Nunemaker 1942); and agglutinins to *Proteus OX* K may be present (Lewthwaite 1940). The bacteriological diagnosis is best made by subcutaneous or

intraperitoneal inoculation of blood taken at the height of a febrile paroxysm, or of serum expressed from the local lesion, into mice and guinea-pigs (Francis 1932). Aspirated peritoneal fluid or blood should be examined daily from the 5th to the 30th day by dark-ground illumination. Brown and Nunemaker (1942) recommend the inoculation of at least 2 guinea-pigs and 4 mice. The guinea-pigs should be inoculated intracutaneously, subcutaneously, and intraperitoneally. Intracutaneous inoculation is sometimes followed by a chancre, and subcutaneous inoculation by enlargement of the regional lymph nodes; in both of these sites spirilla may be demonstrated by dark-ground examination. It is important to remember that mice and less often guinea-pigs may be healthy carriers of *Sp. minus*, so that it is wise to take precautions against confusion resulting from this cause.

Numerous strains of *Spirillum minus* have been isolated from mice, rats, and human patients; according to Schockaert (1928) they are all similar, constituting a single species. In Japan about 3 per cent. of house rats appear to carry the organism (Futaki *et al.* 1917). According to Manuouélian (1940) the spirilla are present in considerable numbers in the muscles of the tongue, which may account for the infectivity of the bite. In the serum of patients who have recovered from rat-bite fever spirochæticidal bodies have been found (Ido *et al.* 1917*b*). Salvarsan or neoarsphenamine usually cuts the fever short, but complete cure of the disease is not always easy to obtain. Recent studies, however, suggest that it may respond to penicillin treatment (Lourie and Collier 1943, Heilman and Herrell 1944*b*).

CHAPTER 83

TYPHUS FEVER AND OTHER RICKETTSIAL DISEASES

THERE must be few diseases about which our knowledge has increased so rapidly during the past two decades as the typhus fever group. Though epidemic typhus has been known for centuries, and has played no small part in determining the course of history it was not till 1909 that Nicolle and his colleagues (1911) first discovered that infection was spread by the body louse, and not till 1916 that da Rocha-Lima demonstrated the ætiological agent of the disease, *Rickettsia prowazeki*. In 1907 Ricketts in the United States had succeeded in transmitting Rocky Mountain spotted fever to guinea-pigs, but the generic relationship of this disease to typhus fever remained obscure till Wolbach (1925) in 1916 demonstrated the rickettsial nature of the causative agent. During the war of 1914–18 a new fever, referred to as Trench fever, was met with; this was likewise found to be due to a species of *Rickettsia*. A sporadic form of typhus fever known as Brill's disease had been recognized for a long time in New York, a severer form known as *Tabardillo* in Mexico, and a milder form in Manchuria and the Far East. Broadly speaking, however, up till 1925, typhus fever was regarded as one of the major epidemic diseases, which in certain areas might sometimes occur in a relatively mild sporadic form. Rocky Mountain spotted fever and Trench fever were regarded as rickettsial diseases due to species of *Rickettsia* entirely different from that causing typhus fever.

In 1925 Fletcher and Lesslar (1925, 1926) found that the endemic typhus fever of the Federated Malay States could be divided serologically and epidemiologically into two entirely different groups, one met with in the towns, the other occurring in country districts. Both differed in certain important respects from the classical type and from each other. These observations provided the main impetus for an extensive and detailed search in various parts of the world for other types of typhus fever. The result has been to reveal the existence in several different countries of endemic typhus fever or typhus-like fevers many of which had previously been unrecognized.

We shall anticipate our discussion on the classification of the various rickettsial diseases of man by describing the diseases themselves, grouping them into four main categories: the typhus fever, spotted fever, tsutsugamushi, and Q fever groups, to which will be added trench fever.

THE TYPHUS FEVER GROUP

Two main varieties of typhus fever are known. The first is often referred to as the classical type; it is caused by *R. prowazeki*, and appears to be invariably louse-borne. The second is called the murine type; it is caused by *R. mooseri*,

and is usually carried to man by the rat flea. Each of these may be briefly considered in turn.

Classical Typhus Fever. *Synonyms:* Fleckfieber, Exanthematische Typhus (German).

This type, though now uncommon in epidemic form in civilized countries, has been in the past one of the great scourges of the world. Like dysentery, it appeared wherever large numbers of people were herded together under insanitary conditions; for this reason it was common in gaols—hence its alternative name " gaol fever "—in military campaigns, and during times of famine. It was specially prevalent in Russia and in Central Europe during the war of 1914–18; and even in the second world war, when protective measures were much better developed, it was a constant cause of trouble and anxiety. The case mortality varies with age. In severe epidemics it is negligible in children, seldom more than 5 per cent. below 20 years of age, about 10–15 per cent. at 40 years, 50 per cent. at 50 years, and generally fatal over 60 years of age (Megaw 1942). Those who wish to realize something of the havoc the disease has wrought among the human population, and of the significant part it has played in determining the outcome of great military campaigns, will do well to refer to the fascinating account given by Zinsser (1935).

In 1909 Nicolle and his colleagues (1911), by experiments on man and on monkeys, showed that the disease was spread by the body louse, *Pediculus corporis*. The louse becomes infected by ingesting the blood of the patient. Within a period varying from about 1 to 2 weeks after feeding, the louse becomes infective, and can transmit the disease to normal persons. The time during which lice may remain infective is not known with certainty, but da Rocha-Lima (1920*a*) has demonstrated their infectivity for at least 24 days, and he believes that they remain infective for the rest of their lives. The great majority, however, of infected lice die within a fortnight It is believed that head lice as well as body lice, but not pubic lice, may act as natural vectors.

The maintenance of infection during non-epidemic times has given rise to much speculation. It is possible that a few mild or symptomless sporadic cases may occur, just sufficient to keep a small number of lice infected (see Kuteischikow *et al.* 1933, Isabolinski *et al.* 1934, Mooser 1941*b*). Alternatively, it is supposed that some persons remain latently infected for considerable lengths of time (see Afanassiewa and Tretjak 1933), and develop a mild disease, perhaps some months after their original infection. The evidence in favour of this second explanation has been carefully marshalled by Zinsser (1934) in his study of *Brill's disease*. This is a very mild form of endemic typhus, which occurs in the north-eastern coastal towns of the United States, and is restricted almost entirely to immigrant Russian and Polish Jews. Zinsser found that infection was caused by the classical type of typhus virus, which must almost certainly have been acquired before the patients had left Europe. The disease represents, in fact, the recrudescence of a latent infection acquired at some earlier time. A third possibility is that infection persists in dried louse fæces attached to patients' clothing and is transmitted to fresh subjects by inhalation. There is reason to believe that the virus may remain alive for a year or more under these conditions, and the high infectivity of airborne rickettsiæ has been amply demonstrated by laboratory observations (see Löffler and Mooser 1942, van den Ende *et al.* 1943).

Bacteriology.

The causative agent of typhus fever is *Rickettsia prowazeki*, first described by da Rocha-Lima in 1916, and later in the same year by Töpfer (1916*b*). Da Rocha-Lima observed this organism in the lice taken from 95 per cent. of typhus patients; it was present in enormous numbers in the intestinal lumen and in the epithelial cells lining the gut wall (Fig. 297). The organisms stain a reddish-purple with Giemsa, are very small, of short elliptic or olive-shape, often in pairs, and are surrounded by a paler staining substance; occasional very short, and very long forms up to 1·5–2 μ, may be seen. They were never found in lice fed on normal persons, or on typhus convalescents, but appeared regularly, and in enormous numbers, in lice fed on typhus patients. The time elapsing between feeding and the appearance of rickettsiæ in the gut depended on the temperature at which the lice were kept; at 23° C. no rickettsiæ appeared at all, but at 32° C. they appeared in about 5 to 8 days, and persisted indefinitely. At about the same time as the rickettsiæ developed, the lice became infective for guinea-pigs. It is important to note that not every louse fed on a typhus patient develops rickettsiæ, or becomes infective. Wolbach, Todd and Palfrey (1922), for example, working in Poland in 1920, fed batches of 30 to 40 lice on typhus patients for an average period of 12 to 16 days, and found that, out of 52 experiments, in only 27 did the lice develop rickettsiæ. In a later series of experiments they also found that only a similar proportion of lice became infective for guinea-pigs. The actual proportion observed was very low, and is probably accounted for by imperfect technique in dealing with the lice; during the latter part of their work the proportion of positive results was considerably higher. Arkwright, Bacot and Duncan (1919) similarly concluded that rickettsiæ do not appear regularly in the excreta of lice fed on typhus patients. Whether this is due to variation in the lice, or, as seems more probable, to the relatively low infectivity of typhus blood, is not known. The significant point is the general parallelism that exists between the presence of rickettsiæ in the louse, and the infectivity of the louse for guinea-pigs.

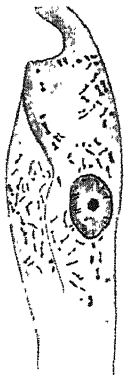

FIG. 297.—*Rickettsia prowazeki*, contained in an epithelial cell from the louse's mid-gut; both coccal and bacillary forms can be seen. Magnification 1,200 diameters (approx.). (After Wolbach, Todd and Palfrey.)

R. prowazeki has been cultivated by Wolbach and Schlesinger (1923–24) in tissue cultures. Small pieces of the brain of typhus guinea-pigs were seeded into normal guinea-pig plasma, and incubated in the usual way over hollow-ground slides. Rickettsiæ were found in the endothelial cells of the vessel walls; primary cultures remained virulent for 8 to 15 days, second generation cultures up to 28 days. The rickettsiæ showed signs of multiplication within the cells; they appeared as coccoid, bacillary, and filamentous forms similar to those found in lice.

Arkwright and Bacot (1923), using Weigl's technique, were able to infect lice by intra-rectal inoculation of a suspension of blood platelets from typhus patients and from infected guinea-pigs. To obtain regular results a thick suspension was

required—platelets from 2 ml. of blood suspended in 6 drops of saline. Similarly successful results were obtained by intra-rectal inoculation of lice with the excreta of infected lice.

Pathologically, both in man and in experimentally infected animals, the brunt of the attack is borne by the blood capillaries, especially those of the skin, skeletal muscles, and central nervous system. The primary site of invasion is the endothelial cells lining the walls of the capillaries. As a result, multiple thromboses occur with perivascular accumulations of cells, often accompanied by small hæmorrhages. In the central nervous system characteristic nodules are found, simulating tubercles. The demonstration of rickettsiæ in human patients is not easy, but they have been found in the lesions of the skin, kidneys, testicles, brain, and other organs in man (Wolbach *et al.* 1922, Wolbach 1925, Cowdry 1926). It will be realized that many of the signs and symptoms of typhus fever, such as the rash and nervous manifestations, are explicable in terms of the vascular lesions.

Relation of Rickettsia prowazeki to Typhus.—It may be well to set out the evidence on which the ætiological relationship of *Rickettsia prowazeki* to typhus is based.

(1) The occurrence of *R. prowazeki* in the characteristic perivascular nodules of typhus; (2) its occurrence as the sole distinctive acquisition of lice fed on typhus; (3) the failure to separate *R. prowazeki* from the virus of typhus by any method yet employed; (4) the cultivation of *R. prowazeki* in lice by the intra-rectal inoculation of a platelet suspension from typhus patients or infected guinea-pigs, even after the virus has been passed several times through guinea-pigs (Atkin and Bacot 1922); and (5) the cultivation of *R. prowazeki* in tissue plasma cultures, using as a source of the virus a strain that had been maintained for 3 years by passage through guinea-pigs: all suggest that *R. prowazeki* is the ætiological agent of typhus (Wolbach 1925). To these we may add that both the typhus virus and *R. prowazeki* are destroyed by exposure to moist heat at 50°–55° C., and that neither is capable of passing through any but the coarsest bacterial filters, and then only irregularly. Against this view it may be said that rickettsiæ are sometimes found in lice taken from persons not suffering from typhus. For example, da Rocha-Lima (1920*a*) found rickettsiæ closely simulating *R. prowazeki* in lice that had been fed on trench-fever patients and on normal persons; Arkwright and Bacot (1923) in Egypt had much the same experience; in some of the lice taken from 2 out of 12 apparently healthy persons they found rickettsiæ simulating *R. prowazeki*. The lice in which they were found were not infective for guinea-pigs, and it is probable that the rickettsiæ were different from those associated with typhus. Da Rocha-Lima considers that the rickettsiæ found on persons not suffering from typhus belong to a different species—generally known as *R. rocha-limæ*. He distinguishes three types of *Rickettsia* in the louse: (1) very fine forms, predominantly intracellular, not very closely packed—*R. prowazeki*: (2) thicker, exclusively extracellular, but lying on the cells—*R. quintana*: and (3) thicker forms, grouped in compact masses, occurring both intra- and extra-cellularly—*R. rocha-limæ*; these may perhaps be pathogenic organisms peculiar to the louse.

It will be seen that the cumulative evidence points very strongly to the ætiological rôle of *R. prowazeki* in typhus. Though rigid adherence to Koch's postulates demands that this conclusion must remain unproven till pure cultures, free from living cells, can be obtained, and used to reproduce the experimental disease in susceptible animals, we shall not depart from justifiable inference if we accept provisionally its essential truth. The onus now rests rather on those who would disprove it than on those who accept it. For a review of typhus fever, see Clavero and Gallardo (1941).

Murine Typhus Fever.

The recognition of an endemic form of typhus fever in the United States, occurring sporadically in man, and spreading not by the louse but by the rat flea *Xenopsylla cheopis*, was due to the brilliant work of a group of American and Mexican workers, prominent among whom were Maxcy, Mooser and Dyer (see Maxcy 1926, 1928, 1929, Mooser 1928, Mooser *et al.* 1931, Dyer *et al.* 1931*a*, *b*, *c*, *d*, 1932*a*, *b*, *c*, Ceder *et al.* 1931, Rumreich 1933). The disease is endemic, occurs in the summer and autumn, is commonest in seaports along the Atlantic border, is not associated with overcrowding, has no predilection for the lower classes, is non-contagious, and has a case mortality of only 1 per cent. It is caused by a virus, often referred to as *R. mooseri*, which differs in some respects from *R. prowazeki*, and which is responsible for causing an extremely mild endemic infection of rats. Sporadic cases in man are liable to occur in persons brought into close contact with these animals, infection being transferred by the rat flea *X. cheopis*. The virus is passed from rat to rat by the rat louse, *Polyplax spinulosus*, and by rat fleas. The rats are never very sick, and the fleas may harbour the virus for over a month and recover—both circumstances indicating a well-established and possibly ancient parasitism (Zinsser 1937). On the other hand, there seems very little doubt that, under suitable conditions, the disease may become epidemic in man and be spread by the body louse. This is apparently what has happened in Mexico where, in addition to sporadic cases of flea-borne typhus, an epidemic disease known as *Tabardillo* occurs. Like classical typhus, it has its maximum prevalence in the winter, is associated with overcrowding, is most prevalent in the lower classes of the population, is contagious, is carried by lice, and has a fairly high case mortality.

The demonstration by American workers of the rôle played by the rat and the rat flea in the spread of endemic typhus was soon followed by the recognition of the disease in other parts of the world. It is called by various local names, such as Toulon typhus, endemic typhus of Moscow, Manchurian typhus, shop typhus of Malaya, and so on. Unlike the classical form, which is commonest in temperate climates, the endemic murine form of typhus tends to be more prevalent in warm countries. Examination of wild rats in numerous areas where the disease is endemic has shown that these animals often give a positive Weil-Felix reaction to *Proteus OX* 19, and that they are latently infected with a murine typhus virus (Penfold and Corkill 1928, Marcandier *et al.* 1931, Kodama and Takahashi 1931, Kodama *et al.* 1932*a*, *b*, Brumpt 1932*c*, Netter 1932, Lépine 1932, Lawton and Murray 1933, Chao-Jen Wu 1933, Kritschewski and Solowiow 1934, Suzuki 1934, Nicolle and Sparrow 1934, Epstein and Silvers 1934, Zinsser 1937, Wolbach 1941 ; see also Tonking 1932–33).

Comparison of the Classical and the Murine Typhus Viruses.—The two viruses of typhus fever, *R. prowazeki* and *R. mooseri*, are very closely related. Both stimulate the production of agglutinins acting on *Proteus OX* 19. Cross-immunity studies have often failed to elicit any difference between them (Zinsser and Castaneda 1930*a*, *b*, 1932, 1934, Zinsser and Batchelder 1930, Mooser and Dummer 1930, Weigl and Hertzig 1933, Mooser *et al.* 1934, Finlayson and Grobler 1940*a*, *b*) ; though there is reason to believe that, at any rate in man, a vaccine prepared with the murine type confers less protection against infection with the classical type than a vaccine prepared from the classical type itself. Their differentiation

is based mainly on the inability of the classical virus to give rise to a scrotal reaction in the guinea-pig or to a febrile disease in the rat (see pp. 934, 935). Pathologically, the two diseases are distinguished by the greater frequency of cerebral nodes in the classical type (see Lillie 1931, Pinkerton 1931). The difference in the case mortality between the two forms may be more a reflection of a difference between epidemic and endemic forms of disease than the result of intrinsic differences between the two viruses. It is known, for example, that in sporadic cases of typhus due to the classical virus, as in Brill's disease, the case mortality is often very low; and that in epidemic typhus due to the murine virus, as in Tabardillo, the case mortality may be high. How far the characters of the two viruses are fixed, it is impossible to say. Probably no one has succeeded in converting one into the other, but temporary modifications can be impressed on them by various means. Whether their behaviour can be so modified that they become indistinguishable is very doubtful, though Mooser (1941*a*) apparently regards this as a possibility.

It may be remarked that both types of virus are highly infective for laboratory workers. Inhalation of infective droplets or dust is very dangerous (see Löffler and Mooser 1942, van den Ende *et al.* 1943). The disease following inoculation of the murine type may vary from a severe to a completely inapparent infection (see Sparrow and Mareschal 1940, van den Ende *et al.* 1943); the disease following the classical type is usually more serious and has proved fatal to several laboratory workers.

THE SPOTTED FEVER GROUP

This group includes Rocky Mountain spotted fever, Brazilian spotted fever (São Paulo typhus), Fièvre boutonneuse, Kenya fever, and South African tick fever. Infection is carried not by lice or by rat fleas but by ticks. There is considerable variation in the severity of these diseases, but they are all characterized by fever and usually by a rash. In fièvre boutonneuse and South African tick fever, but not in the other three forms, there is a primary sore at the site of the tick bite, accompanied by inflammation of the regional lymph nodes. Other tick-borne rickettsial fevers, whose relationship to the spotted fever group is not very clear, have been described in India (see Megaw 1921, 1924, 1930, Boyd 1935, Covell 1936, Topping *et al.* 1943). In addition, there are a number of tick-borne diseases in North America—excluding tick-borne tularæmia and relapsing fever—the origin of which remains obscure, such as Tick paralysis, Colorado tick fever, and Bullis or Lone Star fever (see Parker 1938, Topping *et al.* 1940, Woodland *et al.* 1943, Humphreys *et al.* 1944, Florio, Stewart and Mugrage 1944).

Rocky Mountain Spotted Fever.

This disease, which has been known for many years, occurs in North America. Two types used to be recognized: a Western type with a case mortality of 70 per cent. or so; and an Eastern type occurring nearer the Atlantic border with a case mortality of only 20–25 per cent. (Badger 1933*a*). Recent workers, however, have cast doubt on this difference and tend to regard them both as one disease (Parker 1938, Wolbach 1941). Rocky Mountain spotted fever affects those engaged in outdoor pursuits. It has a striking seasonal incidence, being commonest during the summer and practically absent during the winter months (Hampton and Eubank 1938). The infecting agent, *Rickettsia rickettsi* (*Dermacentroxenus*

rickettsi), is carried by ticks. The Rocky Mountain wood tick, *Dermacentor andersoni* Stiles, seems to be mainly concerned in the west and the American dog tick, *Dermacentor variabilis*, in the east (Dyer *et al.* 1931*e*). Some cases—usually mild—appear to result from the bite of the rabbit tick, *Hæmaphysalis leporis-palustris*, which is very widespread (see Parker 1938); and there is evidence that others may follow the bite of the Lone Star tick, *Amblyomma americanum*—so called from the star-shaped marking on its back—which occurs on dogs and cats, and which bites man in all stages of its development from the larva to the adult (Parker *et al.* 1943). The severity of the disease varies greatly. In mild cases the incubation period ranges from 3 to 14 days, in severe cases from 2 to 5 days. The fever lasts as a rule for 2 to 3 weeks. Convalescence is prolonged.

Ricketts (1907) was successful in transmitting infection to guinea-pigs and monkeys. Besides showing a febrile reaction, inoculated guinea-pigs often develop swellings and hæmorrhages of the scrotum and ears, which may go on to necrosis; the spleen is considerably enlarged (see Munter 1928). The Western type often proves highly fatal to guinea-pigs. Rabbits also develop a febrile disease and sometimes a scrotal reaction; introduction of the virus into the anterior chamber of the eye is less often followed by an acute reaction than occurs with the scrub typhus or tsutsugamushi virus (Lewthwaite and Savoor 1936*c*). Rats and mice can be infected, but the disease pursues a symptomless course (Fukuda 1929).

In human and animal lesions the organisms are found with comparative ease. The lesions themselves resemble those of typhus, but according to Lillie (1931, 1941), endovascular proliferation, degeneration, and thrombosis tend to be commoner. Moreover, in Rocky Mountain spotted fever the medial coat of the blood vessels is said to be affected as well as the endothelial lining (see Wolbach 1941). The blood vessels of the skin and reproductive organs suffer most severely.

The organism can be grown in tissue culture, and is distinguished from *R. prowazeki* by its multiplication in the nuclei of infected cells, where it forms compact spherical colonies (Pinkerton and Hass 1932). The typhus virus multiplies only in the cytoplasm. In the tick the organism presents three forms: (1) an intracellular bacillus-like form, without chromatoid granules, present only in the cytoplasm of the cells of the alimentary tract; (2) a relatively small, rod-shaped form with chromatoid granules, present within the cells and the nuclei of many tissues; (3) a relatively large lanceolate diploid form, which persists in the tissues, notably the salivary glands, long after the other forms have disappeared; this lanceolate form is characterized by its chromatoid staining reaction; it is the only form found in the eggs of infected ticks (see Wolbach 1925). It may be noted that ticks, once infected, are able to hand down infection to their progeny.

Brazilian Spotted Fever.—SYNONYM: São Paulo Typhus.

In its general symptomatology and high case mortality—70 per cent. or so—this disease resembles the severe type of Rocky Mountain spotted fever. Likewise, the Brazilian virus is similar to the Rocky Mountain virus in its peculiarly high pathogenicity for guinea-pigs and in the necrotic scrotal reaction to which it often gives rise in these animals and in rabbits. Inoculation into the anterior chamber of the rabbit's eye is not usually successful in causing an acute reaction; the guinea-pig's eye, however, is very much more susceptible, and an inflammatory reaction associated with corneal opacity develops 2–5 days after inoculation (Monteiro 1931, Dyer 1933). Cross-immunity tests leave little doubt that the São Paulo virus is identical with the virus of Rocky Mountain spotted fever (Dyer

1933, Parker and Davis 1933). Infection appears to follow the bite of the tick *Amblyomma cajennense* (Monteiro *et al.* 1932). (For general account of disease see Piza *et al.* 1932, Fialho 1932.)

Fièvre boutonneuse.

This disease, which was first described by Conor and Bruch (1910), occurs in Tunis and in certain other parts of the Mediterranean littoral. It appears to be identical with the *exanthematic fever of Marseille.* The name " boutonneuse " refers to the local nodule that is so often seen on the leg in the early stage of the disease. The clinical course is brief and mild, and the mortality is low. Infection is carried by the dog tick, *Rhipicephalus sanguineus.* Dogs serve as the reservoir of the virus. As many as 30 per cent. of these animals may be latently infected. Dog ticks may remain infective for several months, and can transmit the virus hereditarily to their progeny. Rickettsiæ have been found in infected ticks, and the name *Rickettsia conori* has been suggested for the causal agent (Brumpt 1932*b*) ; but since this organism is indistinguishable in tissue culture from the Rocky Mountain spotted fever virus (Hass and Pinkerton 1936), and since there appears to be complete cross-immunity between the two diseases (Badger 1933*b*, Blanc and Baltazard 1937), it is doubtful whether it is justifiable to accord it a specific name. Intraperitoneal inoculation of guinea-pigs often gives rise to a mild scrotal reaction (see Blanc and Caminopetros 1931, Durand 1931, 1932, 1933, Durand and Conseil 1931, Durand and Laigret 1932, Nicolle and Laigret 1932, Brumpt 1932*b*, Caminopetros and Contos 1932, 1933, Combiesco and Zotta 1932, Petzetakis and Karalis 1933, Combiesco 1934).

Kenya Fever and South African Tick Fever.

Neither of these diseases has been studied adequately. Kenya fever resembles fièvre boutonneuse, but differs from it in the absence of a primary sore. Infection appears to be carried by the dog tick, *Rhipicephalus sanguineus* (see Roberts and Tonking 1933).

South African tick fever is usually a mild disease, with a case mortality of only 1–2 per cent. It is characterized by a primary sore at the site of the tick bite and by regional adenitis. Infection is transmitted by the larvæ of three different ticks —*Amblyomma hebræum, Rhipicephalus appendiculatus,* and *Böophilus decoloratus*—and by all stages of the dog tick, *Hæmaphysalis leachi* (see Gear 1941). The virus gives rise to a mild fever in guinea-pigs, with little or no scrotal reaction. It can apparently be cultivated on the chorio-allantoic membrane of the developing chick embryo (Alexander, Mason and Neitz 1939). According to Pijper (1936) no cross-immunity exists between tick-bite fever and fièvre boutonneuse, and according to Pijper and Crocker (1938) there appears to be little relation between tick-bite fever and Rocky Mountain spotted fever. Both of these conclusions, however, are disputed by Mason and Alexander (1939*a*, *b*), who regard tick-bite fever as a member of the spotted fever group, and suggest that the virus should be given the varietal name of *pijperi.*

THE TSUTSUGAMUSHI GROUP

Three diseases have been described as belonging to this group : the tsutsugamushi fever of Japan, the scrub typhus of Malaya, and the mite typhus of Sumatra. There is evidence, however, that all three are essentially the same disease, caused by the same organism.

Tsutsugamushi, sometimes known as *Japanese river fever* or *Kedani*, occurs in Japan. It is commonest in the summer and autumn months; it is confined to certain localities, particularly to low-lying territory subject to flooding; and it follows the bite of *Trombicula akamushi* Brumpt—a mite found on the vole, *Microtus montebelloi*. This animal constitutes the reservoir of infection. The causative agent is *Rickettsia nipponica* (*R. orientalis, R. tsutsugamushi, R. akamushi*). It can be grown in tissue culture, but, unlike the spotted fever virus, it does not invade the nuclei. The disease is characterized by fever, a local swelling at the site of the puncture wound, enlargement of the lymph nodes and spleen, and a rash. The incubation period is about a week, and the case mortality is said to be 40 per cent. (Ogata 1931).

Scrub typhus is a disease met with in Malaya. It occurs at all times of the year; it attacks those who have been over country covered with a tall grass, known locally as lalang; infection follows the bite of *Trombicula deliensis*—a mite closely allied to, if not identical with, *Trombicula akamushi*—and rats appear to constitute a reservoir of infection (Lewthwaite and Savoor 1936*d*, 1940*b*). The incubation period is said to be 11–21 days, the duration of fever about a fortnight, and the case mortality 5–15 per cent. In the past it has been stated that this disease is distinguished from tsutsugamushi by the absence of an initial sore at the site of infection; but Lewthwaite and Savoor (1936*e*), who made special observations on this point, found that a sore was commonly present in Europeans, but was very apt to be overlooked on the dark-skinned Tamil. Moreover, a primary sore cannot uniformly be demonstrated in tsutsugamushi itself. It would appear as if the dermal lesion in the two diseases was subject to variation, being conspicuous necrotic and persistent in some cases, inconspicuous papular and fleeting in others.

Mite typhus is a disease met with in the Dutch East Indies, particularly in Sumatra. It closely resembles scrub typhus, but is nearly always characterized by the occurrence of a primary sore. Both the house rat, *Mus concolor*, and the field rat, *Mus diardii* (see Zinsser 1937), appear to constitute a reservoir of infection for the mite vector, *Trombicula deliensis*.

The viruses of these three diseases all closely resemble each other in being comparatively non-infective for guinea-pigs, in producing an inapparent infection in white rats, in causing a severe reaction in the rabbit's eye after intra-ocular injection, and in giving rise to a local necrotic lesion accompanied by fever on intradermal inoculation into the monkey. The serum of convalescent monkeys and rabbits agglutinates *Proteus OX* K but not *OX* 19. The serum of convalescent patients behaves similarly, though the serum of tsutsugamushi patients is said to agglutinate *Proteus OX* K to a lower titre than that of scrub fever or mite fever patients (Wolff 1931*a*, Kawamura *et al.* 1935). Cross-immunity experiments in the rabbit indicate the very close relationship of the three viruses to each other (see Nagayo *et al.* 1930, Kawamura and Imagawa 1931, Wolff 1931*b*, Kouwenaar and Wolff 1933, 1934, 1935, 1936, Wolff and Kouwenaar 1933, Lewthwaite and Savoor 1934, 1936*a*, *c*). Kouwenaar and Wolff (1936) are of the opinion that mite fever and tsutsugamushi can be distinguished by monkey inoculation. The observations, however, of Lewthwaite and Savoor (1936*e*, 1940*a*) seem to leave little doubt that there is complete cross-immunity between the three diseases.

If we accept this finding, we must follow Lewthwaite and Savoor (1940*b*) in giving up the terms " scrub typhus " and " mite typhus " in favour of the general term " tsutsugamushi." For a review of this disease see papers by Ogata (1931, 1935), Nagayo and his colleagues (1931), Lewthwaite (1936), and Lewthwaite and Savoor (1940*b*), and for a list of mite vectors see Williams (1944).

THE Q FEVER GROUP

Observations by workers in Australia and the United States have revealed the existence of a rickettsial tick-borne disease differing in several respects from spotted fever. Derrick (1937) described a disease, under the name of Q fever, affecting abattoir workers and dairy farmers in Queensland. The incubation period of the disease appears to be 15 days or less, the duration of illness 7 to 24 days, and the case mortality nil. Clinically, the outstanding feature of the illness is severe headache; there is no primary sore, and a rash is unusual. The Weil-Felix reaction is negative. Inoculation of guinea-pigs with the patient's blood taken during the febrile stage gives rise to a pyrexial reaction, which leaves the animal immune. Infection of rats, mice, and rabbits is of the inapparent type (Cox 1940). The virus can be demonstrated in the liver of the guinea-pig, and can be cultivated on the chorio-allantoic membrane of the developing chick embryo. Multiplication seems to occur both intra- and extra-cellularly; the nucleus of tissue cells is not, as a rule, invaded; and the virus itself can pass through Berkefeld W and N filters, but not through a Seitz disc. The natural reservoir of infection appears to be in bandicoots and opossums (Report 1938–39), among which continuity of infection is assured by infestation with the tick, *Hæmaphysalis humerosa* (Smith and Derrick 1940). Infection of man occurs indirectly. The scrub tick, *Ixodes holocyclus*, transfers infection from bandicoots to cattle, and so leads to infection of the cattle tick, *Boöphilus annulatus*, which excretes the virus in its fæces. The dried tick fæces are then inhaled by man, pneumonitis being a common primary symptom of the illness (Burnet 1942). For a description of the epidemiology of the disease in Queensland, the reader is referred to a review by Derrick (1944).

The discovery of the disease in the United States was due to Davis and Cox (1938) who, in 1935, demonstrated a filter-passing agent in wood ticks, *Dermacentor andersoni*, collected near Nine Mile Creek, Montana. Parker and Davis (1938) described its experimental transmission by the tick. Dyer (1938) reported the occurrence of infection in a laboratory worker, and later (1939) pointed out the close relationship of this disease to the Q fever of Australia. Cox (1939) suggested the name *Rickettsia diaporica* for the causative organism, but this was later abandoned in favour of *R. burneti*, which had been proposed shortly beforehand by Derrick (1939). The American virus is said to be more virulent for laboratory animals than the Australian virus, but there appears to be complete cross-immunity between the two diseases (Dyer 1939). Several laboratory infections have occurred, but whether these have been due to direct contact with infected tissues, to dust, or to the blood-sucking mite, *Lyponissus bacoti* Hirst, which infests mice, is not clear (see Burnet and Freeman 1939).

TRENCH FEVER

SYNONYMS : *Febris wolhynica : Febris quintana.*

Trench fever is a disease to which attention was first attracted in 1915, when it broke out in epidemic form amongst the troops in nearly every fighting area in Europe. Later it spread to Mesopotamia. The first account of it was given in this country by McNee, Renshaw and Brunt (1916), who called it Trench fever, and in Germany by Werner (1916) and His (1916), who called it Five-day fever and Wolhynian fever respectively. It was proved to be infective, because healthy men developed the disease when inoculated with the blood of patients suffering from it (McNee *et al.* 1916). The blood was found to be infective on the 1st day of the disease, and to remain so until at least the 51st day. Evidence was obtained that the virus was free in the blood plasma and was extra-corpuscular, but that, when the blood was allowed to clot, the virus was entangled in the fibrin and could not usually be demonstrated in the serum. Blood from trench fever patients generally gave rise to the disease in normal persons when inoculated intravenously or intramuscularly, but not when rubbed on to the scarified skin. Clinical and epidemiological evidence suggested that the disease was spread by body lice, and experimentally it was found that if lice were allowed to feed on trench fever patients and subsequently transferred to normal persons, the latter developed the disease.

Lice fed on trench fever patients do not become infective for about 5 to 9 days, but once they have become infective, they remain so for at least 4 months. The virus is found to be present in the louse's excreta, and inoculation of these excreta is one of the best methods of transmitting the disease to man—much more certain than injection of blood. By this method the War Office Trench Fever Investigation Committee (see Bruce 1921) showed that patients suffering from trench fever might retain the power of infecting lice fed on them up to at least 443 days after the onset of the disease. The infectivity of the louse's excreta is very high ; 1/10 mgm. has sufficed to give rise to the disease when inoculated into man. The virulence of the excreta is destroyed by dry heat at 100° C. in 20 minutes, and by moist heat at 60° C. in 20 minutes.

It is very doubtful whether laboratory animals are susceptible to the disease ; a small proportion of guinea-pigs may develop a low undulating type of fever after inoculation with infective material, lasting for several weeks, but infection cannot be transmitted by passage to fresh animals (da Rocha-Lima 1920*b*). On the other hand, human beings are almost all susceptible to the disease. One attack seems to produce only a partial and limited immunity ; a certain proportion of patients who have recovered from one attack may be reinfected by inoculation of blood or of louse excreta 4 or 5 months later (Bruce 1921).

In 1916 Töpfer (1916*a*) described the finding of small short rods, often arranged in pairs and often showing bipolar staining, in lice taken from trench fever patients. The rods were shorter and thicker than those seen in typhus, were present in enormous numbers, and were often arranged in heaps. Töpfer fed lice on 7 trench fever patients, and found these bodies in lice taken from 6 of them ; they did not appear till the 5th day after feeding, but from the 8th day onwards they were found in large numbers. They were never observed in lice fed on healthy persons. These bodies are now known by the name of *Rickettsia quintana.*

Töpfer's findings have been confirmed and amplified by a number of workers. Arkwright, Bacot and Duncan (1919–20) found that rickettsiæ appeared in lice 5 to 12 days after feeding on trench fever patients, and could be demonstrated in the excreta up to the death of the louse. Not all lice became infected at the same time; after feeding on a patient, only a few lice were found to be infected by the end of the 1st week; during the 2nd week the numbers infected and uninfected were about equal, while after the 2nd week the majority showed rickettsiæ. The organisms were found in large numbers crowding the region of the epithelial cells lining the gut; they were always extracellular in position. In any given batch of lice rickettsiæ developed at about the same time as the louse's excreta became infective—as judged by human inoculation. Moreover a very close correspondence was found between the presence of rickettsiæ and the infectivity of the louse, and the absence of rickettsiæ and its non-infectivity. Rickettsiæ were almost invariably found in batches of lice fed on trench fever patients, but only very rarely when fed on normal persons—one positive result out of 245 specimens.

Rickettsia quintana has never been demonstrated satisfactorily in man, and until this has been done, and until the organism has been grown in pure cell-free cultures, it will be impossible to be certain that it is the cause of trench fever. But the observations just quoted on lice strongly suggest that this organism is responsible for the disease.

The remarkable observations made on himself by Bacot (1921) lend support to this view. Bacot went to Poland in February, 1920, with the Typhus Research Commission, taking his own stock of lice with him—a stock that had been under his personal observation and fed upon himself exclusively since November, 1915. During the whole of this time rickettsiæ had never been demonstrated in these lice. In April, after visiting a bath-house in Warsaw, he contracted trench fever. Eight days later, he recommenced feeding his lice; rickettsiæ indistinguishable from *R. quintana* began to appear, and from the 12th day onwards all the boxes of lice proved to be heavily infected. Bacot's blood remained infective for at least 3 months after the clinical termination of his attack. Of the lice collected at the bath-house 7 per cent. proved to be infected with rickettsiæ, which were situated extracellularly, and which were indistinguishable from *R. quintana*. Bacot considers that these lice had probably become infected from apparently healthy persons who had some time previously suffered from trench fever. The importance of this observation lies in the interpretation to be put on the discovery of extracellular rickettsiæ in lice which have had no apparent contact with trench fever patients. Are they to be regarded as a distinct species, peculiar to the louse—as da Rocha-Lima (1920*a*) thinks—and called *R. pediculi* or *R. rocha-limæ*; or are they, in many cases, to be regarded as *R. quintana*, which has gained access to the louse from probably healthy carriers of trench fever? Bacot clearly favours the latter view.

A few cases of trench fever were recognized after the war of 1914–18, and there is reason to believe that the disease is endemic in Poland and Russia (Laurell 1933, Braslawsky 1934). During the second world war numerous outbreaks were reported in the German army on the eastern front, but little new was learnt about the ætiology of the disease (see Marie 1943). The reaction of patients' sera in the Weil-Felix test is still doubtful.

Classification of the Rickettsial Diseases of Man.

Attempts have been made to classify the rickettsial diseases on the nature of the transmitting vector (Megaw 1921, 1930), and on the animal reservoir of infection (Megaw 1942). Besides breaking down at a number of points, such classifications are unsuitable for bacteriological purposes. Felix (1935, 1942*a*) believes that a satisfactory classification can be based only on the antigenic type of the

causative organism, upon which immunity and immunity reactions depend. On the whole, we are in general agreement with this proposal, but we consider it desirable to take into consideration other properties than the antigenic structure alone, such as the morphology of the different viruses, their mode of growth in tissue culture, their infectivity for man and animals, and the type of disease and the pathological lesions to which they give rise. Unfortunately our knowledge is still too fragmentary to enable us to make more than a tentative subdivision on this basis, but the scheme given in Table 182 may serve to indicate the main lines which such a classification should probably follow.

Within the four main groups—excluding trench fever, about which our knowledge is very scanty—there are sub-groups often associated with a particular host, vector or locality. The corresponding viruses tend to differ, particularly in their degree, of pathogenicity for man and laboratory animals. So far, experimental workers have not been successful in converting one sub-type into another, though Mooser, Varela, and Pilz (1934) and Mooser (1941*a*) seem to regard the classical and murine types of the typhus virus as interchangeable.

Diagnosis.

Since the demonstration of the causative organism by growth in tissue culture, the developing chick embryo, or the louse's gut is a lengthy procedure, possible only under favourable conditions, recourse is had mainly to an agglutination test on the patient's serum. The only diagnostic test of importance is the Weil-Felix reaction. In 1916 Weil and Felix, working in Eastern Galicia, cultivated from the urine of a patient with typhus a proteus-like organism that had the peculiarity of being agglutinated not only by the patient's serum but also by the sera of other patients suffering from typhus. Similar organisms were isolated from the urine or the blood of a number of other typhus patients; these were called *Proteus X* strains; the most highly agglutinable of them, and the most specific for typhus, was the *Proteus X* 19 strain (Felix 1916). This strain was agglutinated to a titre varying from 1/50 to 1/50,000 by typhus sera, and never above 1/25 by serum from non-typhus patients. Agglutinins appeared in the blood about the 4th day, and increased up to an acme about the end of the second or beginning of the 3rd week; during convalescence they fell off rapidly, and after 5 months they had disappeared almost entirely. A positive reaction at 1/25 during the 1st week of the disease was regarded as a presumptive positive, though about 7–9 per cent. of persons not suffering from typhus were found to react at this titre. As a rule the titre rose rapidly, so that a positive diagnosis, 1/50 or higher, could generally be made by the 8th day.

The Weil-Felix reaction has now been employed on a large scale, and has been found remarkably valuable. As with many other serum reactions used in diagnosis, experience of it has brought to light certain anomalies and limitations that were not at first realized. Many workers have doubted its specificity, and have brought evidence to show that the reaction may be positive during the course of other infections, and even in healthy persons.

Savoor, Castaneda, and Zinsser (1935), for example, in the United States, found that 25 out of 596 sera from various sources reacted positively in a titre of 1/80, and 4 in a titre of 1/160 (see also Peverelli 1930, Kraus *et al.* 1931, Isabolinski *et al.* 1934, Welch *et al.* 1934). In some of these instances it is probable that the patient had recently recovered from typhus fever, or was suffering from it in a mild or latent form. Sonnenschein (1943) has recorded titres of 1/200 to 1/1600 to *Proteus OX* 19 in patients suffering from *Proteus*

TABLE 182

TENTATIVE CLASSIFICATION OF THE RICKETTSIAL DISEASES OF MAN (Modified from Felix 1942*a*).

Group.	Typhus	Spotted Fever.	Tsutsugamushi	Q Fever.	Trench Fever
NAME OF DISEASE	Classical epidemic typhus. Mexican typhus (Tabardillo). Brill's disease. Endemic typhus of U.S.A., Australia, Greece, Syria, Manchuria, etc. Shop typhus of Malaya. Fièvre nautique of Toulon.	Rocky Mountain spotted fever. Brazilian spotted fever (São Paulo typhus). Fièvre boutonneuse. Kenya fever. Tick-borne fever of South Africa, and probably of India.	Tsutsugamushi. Scrub typhus of Malaya. Mite typhus of Dutch East Indies.	Q fever of Queensland. Q fever of North America.	Trench fever. (Wolhynian fever, Febris quintana).
VECTOR . .	Lice and rat fleas.	Ticks.	Mites.	Ticks.	Lice.
RESERVOIR OF VIRUS.	Rats. Man.	Rodents. Dogs. Sheep.	Voles. Wild rats.	Bandicoots. Opossums. Dogs. Cattle.	? Man.

Grows mainly in the nucleus. No extracellular growth.	*R. nipponica*. Non-filtrable. Grows only in the cytoplasm. No extracellular growth.	*R. burneti*. Filtrable. Grows mainly in the cytoplasm. Some extracellular growth.	*R. quintana*. Non-filtrable. Not yet cultivated *in vitro*.
AGGLUTINATION	*OX* 19 +++. *OX* 2 +. *OX* K −	*OX* 19 +. *OX* 2 +. *OX* K +	*OX* 19 −. *OX* 2 −. *OX* K +++	*OX* 19 −. *OX* 2 −. *OX* K −	?
SUSCEPTIBLE ANIMALS	Febrile reaction in guinea-pigs; scrotal reaction with *mooseri* variety. Inapparent infection in rats. Classical variety dies out in mice. Rabbits insusceptible. Cross-immunity between classical and murine types probably not quite complete. Some degree of cross-immunity between typhus fever and spotted fever.	Usually severe disease in guinea-pigs, often with hæmorrhagic necrosis of scrotum and ears. Febrile disease in rabbits. Inapparent disease in mice and rats. Cross-immunity complete between Rocky Mountain and Brazilian spotted fever, and fièvre boutonneuse; incomplete with South African tick-borne fever.	Relatively non-infective for guinea-pigs, but may produce ascites. Acute reaction after intra-ocular injection of rabbits. Rats and mice difficult to infect. Cross-immunity complete between all three diseases.	Febrile disease in guinea-pigs, but no scrotal reaction. Inapparent infection in mice. Rabbits insusceptible. Cross-immunity between the two diseases complete.	Not transmissible to laboratory animals.

infections such as pyelitis, cystitis, cholecystitis, pleuritis, and bronchitis, as well as in patients with *Proteus*-infected wounds; and Smith and Evans (1943) have noted a raised and fluctuating titre in the course of other diseases like undulant fever, enteritis, typhoid fever, and dysentery (see also de Moor 1936, de Roda 1937).

It follows that the result of the Weil-Felix test should be interpreted strictly in relation to the clinical findings. Generally speaking, it may be said that, except in endemic areas or in patients who have previously suffered from typhus fever or been inoculated against it, complete agglutination of *OX* 19 in a final dilution of the patient's serum of 1/100 or over during the second week of the disease is highly suggestive of active infection. Cases, however, do occur in which the antibody response is very poor or transient, and in which the result of the test has to be regarded as doubtful or negative. Repeated examinations at intervals of 3 or 4 days are of value in detecting transitory reactions and changes in titre indicative of active infection. A strong reaction is regarded by Maly (1942) as a good prognostic sign; a positive reaction becoming negative during the course of the disease as indicative of severe toxæmia and a fatal outcome. According to Felix (1944), however, a low titre may occur not only in very severe, but also in very mild cases. In murine typhus the titres tend to be lower than in the classical form (Findlay 1941). Diagnosis in an inoculated patient does not differ materially from that in an uninoculated patient. Inoculation with the chick embryo vaccine is said not to stimulate agglutinins for *Proteus OX* 19 (Report 1945). If residual agglutinins are present as the result of inoculation with other types of vaccine, they are usually present in very low titre. A rising titre for *OX* 19 therefore is highly suggestive of active infection (Felix 1944).

It is important to realize that agglutination of the O antigen alone of *Proteus* is indicative of typhus infection. Normal agglutinins to the H antigen of *Proteus* strains are not uncommon and have no significance in the diagnosis of typhus fever. In practice, it is therefore wise to work with suspensions prepared from a non-motile *Proteus X* 19 strain, so as to avoid confusion caused by flagellar agglutinins. For this purpose, the formolized suspensions described by Bridges (1935), and issued by the Oxford Standards Laboratory, are most suitable. Agglutination of a non-motile strain, or agglutination of the small flake type of a motile strain, is best referred to as agglutination of *Proteus OX* 19. The test itself is usually carried out by the tube method, but for rapid diagnosis and in epidemiological surveys the slide agglutination method may be used (see Eyer and Grützner 1940, Steuer 1942). Pure suspensions of rickettsiæ, prepared from the lungs of white rats or mice or in some other way, may be used instead of *Proteus OX* 19 (see Hudson 1940), but seem to present little advantage for ordinary routine work.

So far we have been considering the diagnosis only of the typhus group of fevers by the Weil-Felix test. A modified form of the test is, however, of value in the diagnosis of tsutsugamushi and of the spotted fever group.

Fletcher and Lesslar (1925, 1926), studying the endemic typhus of the Federated Malay States, observed that the Weil-Felix reaction to *Proteus OX* 19 was positive in some cases but not in others. Wondering whether their strain of *Proteus X* 19 was losing its agglutinability, they tried a fresh strain that had been brought out to the Straits Settlements by Dr. Kingsbury from the Middlesex Hospital. This strain, which may be referred to as *Proteus X* K, was found to be agglutinated by the sera of patients which failed to react with the *X* 19 type. It was further

observed that sera which reacted to *OX* 19 did not agglutinate *OX* K. There was clearly some distinct serological difference between the two groups of typhus cases. The Kingsbury strain, it may be noted, was reputed to be a strain of *X* 19, but undoubtedly differed from this type antigenically. Further work (see also Fletcher 1930, 1932) showed that the typhus patients whose blood agglutinated *OX* 19 were to be found mainly in urban areas, particularly in shops and storehouses, while those whose blood agglutinated *OX* K came from country districts, especially places where rank grass and scrub had grown up on land which had been cleared of jungle. Fletcher referred to the former type of typhus as urban or *shop typhus*, and to the latter as rural or *scrub typhus*.

We have already described how the urban or shop typhus is carried by rats and is of the ordinary endemic murine type, whereas rural or scrub typhus appears to be identical with the tsutsugamushi disease of Japan. Further experience has confirmed the value of the agglutination of *OX* K in the diagnosis of the tsutsugamushi group of fevers. *Proteus OX* K tends to be agglutinated more often and to a rather higher titre by normal sera than *OX* 19 (see Report 1942), so that complete agglutination in a final dilution of the patient's serum of 1/200 should be demanded for diagnostic purposes. Even then, great care must be exercised in interpreting the result.

A strain of *Proteus X* corresponding to the virus of the spotted fever group has not yet been discovered, but a reaction, often not appearing till late in the second week, may occur with one or more of the *Proteus OX* 19, *OX* 2, or *OX* K strains. Davis, Parker and Walker (1934) found that 77 per cent. of sera taken between the 10th and 32nd days of illness agglutinated *Proteus OX* 19 to 1/160 or over; when two samples were taken at suitable intervals, 95 per cent. of sera proved positive. According to Davis and Parker (1938) a relatively high *OX* 19 and a relatively low *OX* 2 titre is the most frequent combination found. Such a result, or agglutination of *OX* 19 alone, may be due to typhus fever; on the other hand, a high *OX* 2 titre, either alone or in combination with a low *OX* 19 titre, is suggestive of spotted fever (see Felix 1942*b*). *Proteus OX* K is usually agglutinated least of all.

In Q fever the Weil-Felix reaction appears to be completely negative, though agglutination of pure rickettsial suspensions, to a variable titre, may be observed in infected patients (Burnet and Freeman 1938).

For a description of the technique and interpretation of the Weil-Felix reaction in different rickettsial diseases, an article by Felix (1944) may be consulted.

A few reports have appeared on the use of the *complement-fixation reaction* in the diagnosis of rickettsial diseases. Castaneda (1936) demonstrated the presence of specific complement-fixing bodies in the serum of typhus patients; and Bengtson (1941) and Bengtson and Topping (1941) confirmed their specificity by showing that, with an antigen prepared from *R. mooseri*, no reaction was obtained with serum from patients suffering from other diseases, including Rocky Mountain spotted fever and Q fever. Plotz and Wertman (1942), using an antigen prepared from *R. rickettsi*, reported positive results with spotted fever but not with typhus sera. It appears, therefore, that the complement-fixation test tends to be more specific than the Weil-Felix reaction. It has, according to Bengtson and Topping (1942), the additional advantage of enabling a retrospective diagnosis to be made more readily, since the fall in complement-fixing bodies is slower than that of *Proteus OX* agglutinating bodies. For the same reason it is said to be of particular

value in the diagnosis of infection of rats with *R. mooseri* (Brigham and Bengtson 1945).

Other methods of diagnosis may sometimes have to be employed. In Rocky Mountain spotted fever, for example, it may be necessary, if the result of the Weil-Felix test is ambiguous, to resort to the so-called *infection test.* This consists in inoculating the patient's blood intraperitoneally into a male guinea-pig to see whether the typical scrotal reaction of swelling, reddening, and sloughing occurs. In severe cases of the disease this test is often positive, but in mild cases little attention can be paid to a negative result. During convalescence the *virus neutralization test,* in which a mixture of *R. rickettsi* and the patient's serum is injected intraperitoneally into guinea-pigs, together with suitable controls, is more likely to be of value. A similar test for the retrospective diagnosis of typhus fever, in which the mixture of virus and serum is injected into the skin of the rabbit, has been described by Giroud (1938), and found by Clavero and Gallardo (1942) to be specific.

Discussion of the Weil-Felix Reaction.

The explanation of this reaction is still obscure.

That the *Proteus X* bacilli are not themselves responsible for the disease is indicated by the following facts: (1) they are found in only a minority of typhus patients; (2) they do not produce experimental typhus in the guinea-pig; (3) they are never isolated from guinea-pigs infected with true typhus virus; (4) guinea-pigs inoculated with *Proteus X* bacilli develop no immunity to the subsequent inoculation of typhus virus; (5) guinea-pigs that have recovered after inoculation of typhus virus are as susceptible as normal guinea-pigs to a lethal dose of *Proteus X* bacilli (Otto 1919).

Felix himself is of the opinion that the two organisms are genetically related and that *Proteus X* must be regarded as a variant of *Rickettsia*, differing from this organism in its morphological, cultural, and pathogenic properties, but resembling it in the possession of a common O antigen (see Chapter 39 and Felix and Rhodes 1931, Felix 1933*a*, *b*, 1935). If this is so, then *Proteus X* 19 may be looked upon as the variant of *R. prowazeki*, and *Proteus X* K as the variant of the *Rickettsia* of scrub typhus. *Proteus X* variants corresponding to *R. rickettsi*, *R. burneti*, and *R. quintana* have not yet been discovered, though it is interesting to note that strains with a dual antigenic structure responding to both *OX* 19 and *OX* K agglutinins have been reported in Tunis (type *S* 24) and in São Paulo (type *X* L) (see Laigret and Durand 1934).

We should be unwise, however, to accept such an explanation without definite proof. Clearly, the most satisfactory evidence would be afforded by a direct demonstration of the change from *Rickettsia* to *Proteus*, either in tissue culture or in the louse's intestine. Attempts to prove the existence of a genetic relationship along these lines have not yet proved successful, though suggestive results have been recorded by Weigl (1923), Anigstein (1933), and Anigstein and Lawkowicz (1939).

As a corollary it would be important to show that *Proteus X* strains were never encountered except in relation to *Rickettsia.* Our available information on this point is not very reassuring.

A number of workers (see Sparrow and Roussel 1936, 1937, van Loghem 1936) have isolated *Proteus X* 19 strains from persons suffering from diseases other than typhus. Sparrow and Roussel, working in Tunis where typhus is epidemic, cultivated organisms of the *X* 19 type from the blood of about 50 per cent. of typhus patients in 1935, and from about 9 per cent. of patients suffering from other diseases, such as undulant fever,

typhoid fever, malaria, and pulmonary tuberculosis; in the following year, however, the proportion of positive cultures was very much lower. It may further be noted that *Proteus* strains have been found in the blood and urine of typhus fever patients which were not of the *X* 19 type (Schürer and Wolff 1919; see also Felix 1931).

Some workers, such as Otto (1919), have regarded the Weil-Felix reaction as an example of para-agglutination, using this term to mean the agglutination of a heterologous organism by virtue of a property conferred on it by contact with the homologous organism. It is supposed that *Proteus* bacilli in the body of a typhus-infected patient gain new antigenic receptors, which render them susceptible to antibodies produced against the typhus virus. If this were true, it would explain the origin of *Proteus X* types corresponding to different rickettsial types; but insufficient evidence has yet been adduced to render this more than a speculation.

A more or less similar conception has been advanced by W. J. Wilson (1909, 1920), who showed that certain coliform bacilli isolated from the urine or fæces of typhus patients were agglutinated more readily by typhus sera than by normal sera. Wilson believes that under the stimulus of infection with the typhus virus, some normal intestinal bacterium calls forth the production of specific agglutinins to itself and of group agglutinins to other organisms, such as *Proteus X* 19. This suggestion receives some support from the observations of Giroud and Tannenbaum (1937). Trying to solve the problem why infected guinea-pigs, unlike rabbits and monkeys, do not give a positive Weil-Felix reaction, these workers observed that *Proteus* bacilli are never found in the guinea-pig's intestine. They therefore infected a group of these animals with typhus virus parenterally and with *Proteus* bacilli by the mouth, and found that their serum developed the property of agglutinating *Proteus OX* 19. Incidentally, it may be noted that, though the serum of typhus-infected guinea-pigs does not agglutinate *Proteus X* 19, it does agglutinate pure suspensions of rickettsiæ (Hudson 1940).

An alternative explanation is that the Weil-Felix reaction is an example of group agglutination (see Fairley 1919–20). It is known (see p. 933) that *Proteus X* 19 and *R. prowazeki* share a common antigen, and so far as these two organisms are concerned, such an explanation is satisfactory. The existence, however, of a similar relationship between *Proteus X* K and *R. nipponica* necessitates the assumption that an antigenic variety of one genus is reflected in a corresponding variety within the other genus. This has been regarded, perhaps unjustifiably, as too much of a coincidence to be probable. It would, perhaps, be less probable if *Proteus X* strains corresponding to *R. rickettsi*, *R. burneti*, and *R. quintana* were known to exist; but so far attempts to find these variants have proved a failure. We are therefore left at present with only two *Proteus X* types corresponding to two rickettsial types, depending, in the case of *R. prowazeki*, upon a similarity in the chemical structure of its glycolipoid antigen with that of the glycolipoid antigen of *Proteus X* 19 (Ciuca *et al.* 1938).

Prophylaxis and Treatment of the Typhus Fevers.

As in other diseases which are purely insect-borne, the prevention of rickettsial infections resolves itself into the control or elimination of the insect vector. In the particular instance of epidemic typhus fever the essential factor is the prevention of the frequent passage of the body louse from man to man; and this is best attained by reducing louse infestation to a minimum, and by the prevention of overcrowding. Typhus is not a disease of which any cleanly and reasonably

prosperous community need stand in dread during times of peace ; its whole history shows its close relation to poverty, malnutrition, overcrowding, dirt, wretchedness, and war. The control of endemic typhus fevers presents a more difficult problem, partly because of the widespread distribution of the various infecting agents, and partly because of the sporadic nature of the disease in human beings. Destruction of the normal animal reservoir of infection, such as the rat, may be more effective than attempts to interfere with the passage of the insect vector to man, though these will generally have to be made in addition. For a description of the hygienic measures required to control louse-borne typhus fever the reader is referred to a paper by Mackenzie (1941) and to a memorandum by the Ministry of Health (Memo. 1941). Neither of these publications, however, makes mention of the extremely effective methods that were introduced during the second world war for the prevention of louse infestation by impregnating the clothing with certain chemical substances. Under some conditions, precautions may have to be taken to prevent infection by the respiratory tract with dried insect fæces or other infective forms of dust.

Chemotherapy has not yet proved of value in typhus fever. Experimentally, Andrewes and his colleagues (1944) have reported favourable results in mice infected with the murine or the classical typhus virus by the use of two sulphamido compounds, but these have apparently no effect on man. Similarly, Greiff, Pinkerton and Moragues (1944) find that both penicillin and para-aminobenzoic acid inhibit growth of the murine virus in the yolk sac of the chick embryo ; human trials with these substances are in progress.

Vaccination.

Attempts to produce active immunity by vaccination have been made by a number of workers. Without reference to chronological order, these may be classified as follows.

Living Vaccines.—Nicolle and Laigret (1936) prepared a vaccine of murine virus from infected guinea-pig and rat brain. The organisms were dried, coated with egg yolk, dried again, and finally suspended in olive oil. Three doses were given. The vaccine has been tried on several thousand persons, mainly natives, with apparently favourable results (Laigret *et al.* 1937). A few cases of inoculation typhus have resulted.

Killed Vaccines.—In preparing a dead vaccine, the problem is how to obtain a thick suspension of rickettsiæ. The following solutions have been proposed.

(*a*) *Weigl's louse vaccine.*—Lice are inoculated by the rectum with the classical typhus virus. After a week or so they are killed ; the intestines are removed and ground up in 0·5 per cent. phenolized saline (Weigl 1933). This vaccine has been used on a fairly large scale and appears to have met with considerable success (see Radlo 1937, Mosing 1938). Since three doses are given, requiring the use of 120–175 lice for each subject, an enormous louse farm has to be maintained if vaccine is to be prepared on any considerable scale. An additional drawback is the necessity for feeding the lice for a week after infection on immune persons.

(*b*) *Killed suspensions of rickettsiæ grown in animals.*—Various methods have been used. (1) Zinsser and Castaneda (1930*a*, 1931, 1933) introduced the intraperitoneal inoculation with a murine virus of guinea-pigs or rats whose resistance had been lowered by injections of benzol, feeding on a vitamin-deficient diet, or best of all irradiation with X-rays (see also Macchiavello and Dresser 1935). In such animals great proliferation occurred in the peritoneum and tunica vaginalis ;

a thick rickettsial suspension could be obtained by washing out the peritoneal cavity, and converted into a vaccine by treatment with 0·2 per cent. formol. This vaccine has had only a limited trial, but according to reports by Veintemillas (1939) in Bolivia and by Finlayson and Grobler (1940*a*, *b*, 1941) in South Africa, it seems to protect not only against the murine virus, but also—provided a large enough dose is given—against the classical typhus virus. (2) Castaneda (1939) found that the lungs of rats which had been inoculated intranasally with a murine virus contained abundant rickettsiæ. A vaccine was prepared by grinding up the lungs of these animals 3 days after inoculation, killing the rickettsiæ with phenol, and obtaining a suspension of the organisms by differential centrifugation. Three doses of vaccine are recommended for man at 7-day intervals (Castaneda 1941). Guinea-pig experiments show that this vaccine protects readily against infection with the murine virus, but only when given in large dosage against the classical virus. (3) Okamoto (1937) observed that rickettsiæ of the murine type were able to multiply in the mouse's lung. Durand and Sparrow (1940) made use of this observation, and found that mice inoculated intranasally with the murine or the classical typhus virus died in 3 to 7 days, and that at post mortem their lungs contained enormous numbers of rickettsiæ. Durand and Giroud (1940*a*) and Giroud and Panthier (1942) prepared a vaccine from a formolized suspension of ground-up mouse lung, and found it to protect guinea-pigs against experimental infection. For human beings 4 or 5 weekly inoculations appear to be required. Rabbit lung and dog lung vaccines have also been used.

(*c*) *Killed suspensions of rickettsiæ grown in tissue culture.*—Zinsser, Fitzpatrick and Wei (1939) have described a relatively simple method of growing rickettsiæ in a modified Maitland medium making use of agar blocks covered with living tissue. The growth can be removed and treated with 0·3 per cent. formol for conversion into a vaccine.

(*d*) *Chick embryo vaccine.*—Cox (1938, 1941) found that much the best method of growing rickettsiæ of typhus fever, spotted fever and Q fever was in the yolk sac of the developing chick embryo. Once strains of the classical typhus virus are established, they usually kill the embryo in 3 to 5 days. The pooled embryonic tissues are then ground up and treated with phenol and formalin. Yolk sac suspensions are 100 to 1,000 times more infective than suspensions of mammalian tissues. The method is very simple and applicable to large-scale production. This vaccine has achieved wide popularity, and was used in the second world war for the inoculation of the British and American forces.

Insufficient controlled observations have as yet been made to enable any sound conclusions to be drawn on the absolute and relative protective value of these different vaccines. Otto and Bickhardt (1942) found mouse and rabbit lung vaccines to be superior to chick embryo vaccines in the protection of guinea-pigs. Ding (1943), on the other hand, who made observations on human beings under what seem to have been almost experimental conditions, was led to conclude that rabbit and dog lung vaccines and chick embryo vaccines were equally satisfactory and yielded results not inferior to those of Weigl's louse vaccine. None of them appeared to protect against the disease itself, but all of them shortened the fever, diminished the nervous symptoms, rendered the illness milder, and conferred a high degree of protection against death. Plenty of other evidence is available to show that vaccination does not prevent an attack of the disease, at any rate if exposure to infection is severe (see Löffler and Mooser 1942, van

den Ende *et al.* 1943). American observations suggest that, judged by animal experiments, the Castaneda rat lung and the Cox chick embryo vaccines are both inferior to Giroud's mouse lung vaccine. Chick embryo vaccine can be improved by the addition of alum (Report 1945). How far a murine typhus vaccine is effective against the classical virus is still in doubt. According to Mooser and Leemann (1941) there is in animals a complete cross-immunity between the two diseases; but there are numerous published and unpublished observations suggesting that this does not hold for man. The question, however, is difficult to answer, since even a vaccine prepared with one type does not afford complete protection against inoculation with the same type. Whatever vaccine is used, repeated single doses at 6-monthly intervals to stimulate the waning immunity are desirable if the risk of exposure to infection continues. (For a description of the mode of preparation of the different vaccines, see Clavero and Gallardo 1943, and for a study of the chick embryo vaccine, in particular, see Report 1945.)

Similar vaccines have been used for inoculation against the spotted fever group. Indeed it was against Rocky Mountain spotted fever that a satisfactory killed vaccine was first produced by Spencer and Parker (1925), when they prepared a phenolized suspension of the viscera of infected ticks. A formolized mouse lung vaccine has been described by Durand and Giroud (1940*b*). Protection of experimental animals against Q fever may be obtained by vaccines prepared from chick embryo tissues or from the fæces of *Dermacentor andersoni* (Cox 1940). Rickettsial suspensions prepared from infected mouse spleens and killed by 0·5 per cent. formol or by heating at 60°–65° C. for 30 minutes are also said to be effective (Burnet and Freeman 1941). Against scrub typhus a vaccine has been prepared by Fulton, but no account of it has yet been published.

Serum Treatment.

Nicolle, Conor and Conseil (1911) found that the serum of human patients or of monkeys convalescent from typhus fever possessed protective and curative properties, when tested on experimental infection in monkeys or the natural disease in man. The serum was most active on the 10th to the 12th day after defervescence; after the 15th to the 20th day it had lost its activity completely, even though the monkey itself was resistant to a fresh inoculation of virus. Nicolle introduced the treatment of the disease by such serum. For *prophylactic* purposes he injected about 3 doses of blood serum, obtained by centrifugalization of the coagulated blood. According to his observations, persons treated by this method subsequently proved resistant to the inoculation of 3 ml. of blood from a typhus guinea-pig. For *therapeutic* purposes the blood serum of convalescent patients may be injected in fairly large quantities. Little is as yet known of the value of this method of treatment.

More recently, Durand and Balozet (1940, 1941) have prepared antiserum by the inoculation of horses and asses with mouse lung suspensions of the murine and classical types, and by animal experiments have found it to be considerably more potent than convalescent human serum. The neutralizing power does not run parallel with the Weil-Felix agglutination titre, since the antigen responsible for the stimulation of neutralizing antibody appears to be the heat-labile, not the heat-stable, rickettsial antigen. In practice, this serum is given therapeutically in a single dose of 100 ml. intramuscularly. The few observations that have so far been made on it suggest that, if given early, it shortens the duration of the illness and diminishes the risk of death (see Wolman 1944). Similar results

have been claimed by Topping (1943) for the treatment of Rocky Mountain spotted fever by a serum prepared by the inoculation of rabbits with infected ticks or yolk sac cultures.

Rickettsial Infection of Animals

Though animals often act as a reservoir of rickettsiæ that are pathogenic for man, little is known as yet of the occurrence of animal disease due to other types. The best example is heartwater.

Heartwater.—Economically, this is an important disease of sheep, goats, and cattle. It is widespread over the whole of Africa, except the northern portion. Infection is due to *Rickettsia ruminantium*, first described by Cowdry (1925), and is transmitted by the tick *Amblyomma hebræum*. Clinically, the disease varies from the hyperacute form, on the one hand, to the abortive form, on the other. The incubation period in sheep is 7 to 14 days. The acute form is characterized by fever, serous effusions in the pleura, pericardium, and peritoneum, and convulsive symptoms. The course is 2–6 days, and the case mortality 50–100 per cent. Cases occur sporadically and in small groups, not in large epidemics (Donatien and Lestoquard 1937). *R. ruminantium*, like the organisms of typhus and of spotted fever, infects primarily the vascular endothelium, and like *R. prowazeki*, but unlike *R. rickettsi*, grows in the cytoplasm, not in the nucleus of the cells. Laboratory animals seem to be relatively insusceptible to infection. No satisfactory method of vaccination against the disease has yet been described, but the disease is said to be susceptible to sulphonamide treatment (Neitz 1940). Some workers regard heartwater as a virus rather than a rickettsial infection and would classify it in the lymphogranuloma-psittacosis-virus-pneumonia group of diseases. The evidence is still inconclusive, and we consider it wiser for the time being to retain it in this chapter.

Other Infections.—Mention has already been made in the chapter on *Rickettsia* (pp. 936–7) of organisms described under the term *R. conjunctivæ* which appear to infect the conjunctival epithelial cells of certain animals, and of organisms described as *R. canis*, *R. ovina*, and *R. bovis* affecting the monocytes. The claim of these organisms to belong to the rickettsial group is still unsubstantiated, and since, with the exception of *R. canis*, the diseases with which they are associated are very benign, we shall deal with them no further.

For a general description of the rickettsial diseases, the reader is referred to reviews by Zinsser (1937), Parker (1938), Lewthwaite and Savoor (1940*b*), and Wolbach (1941).

CHAPTER 84

PLEUROPNEUMONIA, CONTAGIOUS AGALACTIA, AND ALLIED DISEASES

PLEUROPNEUMONIA OF CATTLE

PLEUROPNEUMONIA is an infectious disease of cattle characterized by an exudative inflammation of the interlobular lymph vessels and of the alveolar tissue of the lungs, with a simultaneous sero-fibrinous pleurisy. According to Nocard and Roux (1898), the essential lesion is a distension of the connective tissue layers between the lobules of the lungs with a large quantity of yellowish, limpid, albuminous, highly infective fluid. The disease is widespread throughout the world, with the exception of Western Europe, India, and North America (Walker 1930). It used to be common in Europe, but preventive measures have greatly decreased its incidence, while in the United States it has been completely eradicated. Epizootics are common in endemic areas; the morbidity is high; the case mortality varies considerably according to the severity of the disease. The mode of infection is not clear, but there is reason to believe that it is carried by droplets, and indirectly through dust particles contaminated with nasal discharge (Tang *et al.* 1935). The causative organism of the disease is characterized by a high degree of pleomorphism and by its filtrability. The disease can be reproduced experimentally by inoculation of cows with infective material or cultures of the filtrable organism (see Chapter 40). Active immunization is practised by inoculation of tissue fluid, or preferably of a living culture of the organism, into the point of the tail. This results, as a rule, in a non-fatal disease, which leaves the animal immune for a year or more. Most workers recommend a strain of modified virulence (Bennett 1932, Mettam and Ford 1939, Purchase 1939), but Kurotchkin (1939) prefers a fully virulent strain. The serum of convalescent animals is used for passive immunization. Not all strains appear to be identical, and it is possible that an animal that has recovered from one attack may prove susceptible to later invasion by a different strain. In practice the slaughter policy is recommended for the control of the disease. In carrying out this policy, the complement-fixation test may be of value in the detection of carriers. According to Bennetts (1937), the test itself is reliable, but the eradication method based on it is not always successful, owing to the long incubation period of the disease and other causes. (For pleuropneumonia of calves due to *Pasteurella septica*, see p. 1647.)

CONTAGIOUS AGALACTIA OF SHEEP AND GOATS

This disease is characterized by inflammatory lesions of the udder, eye, and joints. The milk yield in lactating animals is diminished, and instead of milk, a

dirty yellow serous fluid containing small clots is secreted (Galloway 1930). Several outbreaks have occurred during the past hundred years in Europe, and more recently the disease has been encountered in North Africa. The case mortality is said to average about 15 per cent. The causative organism, which was first cultivated by Bridré and Donatien (1923, 1925), resembles the organism of pleuropneumonia in its pleomorphism and its filtrability. Natural infection usually appears to occur by ingestion. The disease can be reproduced by inoculation, especially of goats, with infected tissue suspensions, and with pure cultures (see Chapter 40). Animals that have recovered naturally from an attack of the disease have a high degree of immunity. Active immunization is very difficult. Passive immunity may be conferred by the injection of immune sera prepared in sheep, goats, or horses (Bridré and Donatien 1925).

DISEASES CAUSED BY OTHER MEMBERS OF THE PLEUROPNEUMONIA GROUP OF ORGANISMS

Numerous diseases of animals have now been ascribed to infection with other members of the pleuropneumonia group, such as arthritis, lymphadenitis, and suppurative lesions in rats, and arthritis and rolling disease in mice. The relation of these organisms to bronchiectasis in rats, distemper in dogs, and certain genital fesions in the human female is still under discussion. Space does not allow a lull description of each of these diseases; adequate attention has already been paid to them in Chapter 40, which the reader may consult for references to the original papers.

CHAPTER 85

FILTRABLE VIRUS DISEASES

A. THE LYMPHOGRANULOMA-PSITTACOSIS GROUP

In this and the following four chapters we describe the most important diseases of man and animals that are caused, or probably caused, by filtrable viruses. We are immediately faced with the problem of their classification. Numerous suggestions have been made by different workers for grouping these diseases according to the tissue attacked, the nature of the lesion produced, the presence of inclusion bodies, the transmissibility of infection, and so on (see Rivers 1932, Fine 1932, McKinley 1934, Fairbrother 1934, Hurst 1936). It is clear that the only satisfactory classification must rest on the nature and properties of the causative viruses themselves. Our knowledge, however, of the viruses is extremely meagre, and though tentative efforts at their classification are doubtless of value in research work, it is perhaps a little premature to reproduce them in what is primarily a textbook designed for teaching. We shall, therefore, omit any serious attempt at classification. The order in which we shall describe the various diseases will be determined partly by their public health importance, and partly by the nature of the organs or tissues mainly attacked. It may be noted that influenza and swine influenza have already been dealt with in the chapter on respiratory infections (Chapter 74).

The viruses described in this chapter fall into a group that appears to be intermediate between the rickettsiæ and the true filtrable viruses. Most or all of them form elementary bodies that take on basic stains and can be readily seen under the microscope; some of them are known to pass through a series of morphological changes during growth; and most of them appear to be closely related antigenically. They differ from the rickettsiæ in being spherical rather than rod-shaped, in having no antigenic affinity to *Proteus OX* strains, and in the absence of an insect host. They differ from the common filtrable viruses in their larger size—usually about 150–300 mμ—in being held back partly or completely by a Berkefeld N candle or a Seitz disc, and in their failure, as a rule, to give rise to a lasting immunity. Some of them are distinguished by their reputed susceptibility to the sulphonamide drugs.

LYMPHOGRANULOMA INGUINALE

Synonyms: Climatic bubo; Lymphopathia venereum; Poradenitis. Not to be confused with Granuloma venereum (see p. 1790).

In 1913 Durand, Nicolas and Favre of Lyons drew attention to a bubonic disease, probably of venereal origin, which was characterized by a subacute inflam-

mation of the inguinal lymphatic glands. In 1925 Frei reported the discovery of a specific intracutaneous test for the diagnosis of the disease. As a result of this means of differentiating lymphogranuloma from other diseases, several workers entered the field of investigation. In 1930 Hellerström and Wassén at the International Dermatological Congress in Copenhagen described the successful transmission of infection to monkeys by intracerebral inoculation, and concluded that the disease was of virus origin. Since then there has been a large outcrop of papers on various aspects of the subject, which it is impossible to summarize adequately in the space at our disposal. Those who are desirous of more detailed information are referred to monographs and papers by Stannus (1932), Koch (1933), Findlay (1933), Hellerström and Wassén (1934), Wassén (1935), Levaditi, Mollaret and Reinié (1935), and Nelson (1941).

Though showing a preference for the tropics, the disease is widespread throughout the world. Males of 20–40 years of age are most often affected. The disease is contracted through sexual intercourse. After healing of the initial penile lesion, males cease to be infectious, whereas females, on account of the peculiar lymphatic distribution in the perineal region, remain infectious for months and years. In females particularly, the disease often involves the genito-ano-rectal tissues with the production of a stricture—a condition referred to as *esthiomène*—though it is not yet established that all cases of esthiomène are caused by the lymphogranuloma virus.

Attention was first concentrated on the local lesions, but the disease is now known to be accompanied by a generalized infection. In its early stages it may even simulate typhoid fever; arthritis and skin rashes are not uncommon, and symptoms suggestive of meningeal affection may occur (Findlay 1938). Congenital transmission of maternal antibodies has been noted, though the virus itself does not appear to pass through the placenta (Levine *et al.* 1943). A few laboratory infections have been reported (Harrop *et al.* 1941). In adults infection may remain latent for months or years. Pathologically, the essential lesion produced by the virus is a low-grade inflammation of the lymph spaces and lymph channels leading to caseation and fibrosis.

Intracerebral inoculation of infective material into monkeys gives rise, after an incubation period of 6–12 days, to meningo-encephalitis. The mouse is also susceptible. After intracerebral inoculation, symptoms appear in 2–4 days; the coat is roughened, the back is hunched, and purulent conjunctivitis may be seen; death occurs in 3–8 days. The virus may be carried on indefinitely by passage, but some strains gradually become inactive. According to Miyagawa and his colleagues (1936*a*), their virulence may be restored by intradermal passage through guinea-pigs, in which the virus produces a caseous papule at the site of inoculation. Intranasal inoculation of mice may give rise to focal lesions in the lungs (van den Ende and Lush 1943). Guinea-pigs and rabbits are relatively resistant to intracerebral infection. Infective monkey or mouse brain, when inoculated on to the prepuce, is able to reproduce the typical disease in human subjects (Levaditi *et al.* 1932, 1935, Wassén 1935).

Ætiology.—The causative virus passes through Berkefeld N and Chamberland L3 candles, though the results are said to be inconsistent. According to Miyagawa and his colleagues (1935*c*) and to Broom and Findlay (1936), its probable diameter is about 0·125–0·175 μ. It is destroyed by exposure to a temperature of 56° C. for 10 minutes, and is readily inactivated by glycerol and by 0·1 per cent.

formol. At 4° C. it remains virulent for about 3 weeks. The virus is difficult to grow in tissue culture (Miyagawa *et al.* 1936*b*), but it can be propagated indefinitely by passage through the yolk sac of the developing chick embryo (Rake *et al.* 1940, 1941). An infection occurs that proves fatal to the embryo in 3 days to 2 weeks. Virus is present in large quantity in the wall of the yolk sac and in the yolk itself. Elementary bodies, demonstrable by histological methods, have been described by various observers in infected tissue from man, monkeys, and mice (for references see Findlay *et al.* 1938). They are sometimes referred to as the granulo-corpuscles of Miyagawa (Miyagawa *et al.* 1935*a*, *b*). Neutralizing antibodies may be detected in the serum of patients suffering from the disease and in the serum of inoculated rabbits. According to Rake and Jones (1944) the virus is able to give rise, when grown in the yolk sac of the chick embryo, to a thermolabile endotoxin killing mice, injected intravenously, in 12 to 24 hours.

Observations by Findlay, Mackenzie and MacCallum (1938) have shown that in the brain of mice the elementary bodies, which stain reddish-purple with Giemsa, swell up to 3 or 4 times their original size, forming large bodies, which take on a bluish-purple tint. These are grouped in a compact morula-like mass, probably intracellular in situation. Later some of the bodies break away and enter other cells. Gradually the large forms disappear, and are replaced by masses of small forms, which may be collected within cyst-like spaces. From these, the small forms or elementary bodies are liberated, and are again capable of infecting fresh cells. This sequence of small and large forms has been described as a developmental cycle, but the picture is so similar to that which is seen in ordinary bacterial cultures (see Chapter 4) that it is probably wiser not to use the expression. For a pictorial representation of cytoplasmic inclusion bodies in the brain of the experimentally infected mouse, the coloured plates in a paper by Ishimitsu (1937) may be consulted as well as those of Findlay and his colleagues. Elementary bodies may likewise be demonstrated in yolk sac cultures (Rake *et al.* 1941).

Diagnosis.—In the diagnosis of the disease the Frei (1925) test is widely used. The antigen consists of pus from a bubo, heated to 60° C. for 2 hours on 1 day, and for 1 hour on the following day. Intracutaneous inoculation of 0·1 ml. gives rise in an infected subject to an infiltrated inflammatory area, at least 0·5 cm. across, with a small central zone of necrosis. The reaction reaches its height after about 48 hours. Injected intravenously, the antigen gives rise to a febrile response; according to Hellerström this method is more sensitive than the original intradermal test.

Owing to the difficulty of obtaining and of standardizing test material of human origin, an antigen for intradermal use has been prepared from mouse brain. It has been reported on favourably by Grace and Suskind (1936). More recently an antigen, known as *lygranum*, prepared from cultures in the developing chick embryo, has been introduced. It is said to give rise to fewer non-specific reactions than the mouse-brain antigen, though a control test with normal chick embryo material must always be carried out (Shaffer *et al.* 1942, Axelrod 1942, Heisel *et al.* 1943). In practice, 0·1 ml. is inoculated intradermally. Readings are made at 48 and 72 hours. A papule not less than 7×7 mm. is regarded as a positive reaction, one less than 5×5 mm. as a negative reaction. The same antigen may be used for a complement-fixation test with the patient's serum. In view of the antigenic affinity of some of the pneumonia viruses (see p. 1875) with the virus of lymphogranuloma, the strict specificity of the skin and complement-fixation reactions must be regarded for the present as open to question (see Blair 1944, Beeson and Miller 1944).

Animal experiments suggest that the disease is susceptible to treatment with the sulphonamides. How these drugs act is unknown. They have no apparent effect on the virus *in vitro* (MacCallum and Findlay 1938), nor can any serious destructive action be demonstrated in the brain of mice, even though mice suffering from meningo-encephalitis are said to be cured by the administration of sulphanilamide or sulphaguanidine (Rodaniche 1942). Clinical experience of these drugs in the treatment of the disease in man has so far been unsatisfactory (Kramer *et al.* 1944).

PSITTACOSIS

This is primarily a disease of birds, which sometimes attacks man. The first human case reported was by Ritter (1879–80) in Switzerland, who described the clinical and pathological features of the disease. Little attention was paid to the disease till 1929–30 when psittacosis appeared in many places throughout the world. In the United States alone 74 foci of infection were recognized, and 169 cases occurred with 33 deaths (Armstrong 1930). The incubation period in man is usually about 6–15 days. The disease resembles typhoid fever in many respects and is often complicated by pneumonia. Infection occurs by the inhalation of infective material excreted by parrots, parrakeets, love-birds (budgerigars), canaries, or other birds. Case-to-case infection is rare. Workers in a laboratory where the virus is being handled are particularly prone to develop the disease (McCoy 1934).

For many years psittacosis was regarded as a disease affecting primarily birds of the parrot family; but in 1938, following an epidemic of pneumonia among the inhabitants of the Faroe Islands, widespread infection was demonstrated among the fulmar petrels (*Fulmarus glacialis*), which breed on the coast and are used by the inhabitants as food (Haagen and Mauer 1938, Rasmussen-Ejde 1938, Bedson 1940). Infection of human beings was four times as common in women as in men, and was apparently contracted by the inhalation of infected dust during the plucking of the birds' feathers. Later, Meyer and Eddie (1942) in the United States found that chickens were infected; and Meyer, Eddie and Yanamura (1942) showed that latent infection was present in pigeons collected from different parts of the States. Indirect evidence of infection of turkeys and ducks has been brought by Eddie and Francis (1942). In this country the isolation of the virus from pigeons has been reported by Andrewes and Mills (1943). It is thus evident that psittacosis is a common avian infection. Usually it appears to remain latent, but under certain conditions it may give rise to clinical disease and prove fatal. Man is infected mainly from parrots and budgerigars, owing possibly to his closeness of contact with these birds.

In parrots the disease is characterized by diarrhœa, shivering, weakness, and apathy. Respiratory disturbances may develop, accompanied by croaking noises and the secretion of mucus. Recovery often occurs, and is followed by a considerable degree of immunity to fresh infection. Latent infection appears to be widespread among parrots, cockatiels, lorikeets, budgerigars, and similar birds in their native countries, while in many aviaries in Europe and America the disease is endemic (Meyer and Eddie 1934, Burnet 1935). Pathologically the disease in parrots is essentially an infection of the liver and spleen with occasional involvement of the lungs. Multiple necrotic areas are found in the liver, and the infective agent is present in the blood, internal organs, nasal discharges, and fæces (Rivers

et al. 1931). Infection can be transmitted experimentally to budgerigars, parrots, mice, rabbits, guinea-pigs, and monkeys by suitable methods of inoculation. In mice continuous passage of the virus is readily accomplished by intraperitoneal inoculation of infected liver and spleen suspensions. The animals become ill and die in 4 to 20 days; pneumonia is uncommon, but characteristic changes occur in the liver and spleen, similar to those in parrots. Injected intradermally into the shaved skin of the rabbit or guinea-pig, the virus gives rise to a local papular eruption similar to that caused by the virus of herpes. Intracerebral injection into monkeys, rabbits, and guinea-pigs is followed by a meningo-encephalitis, but intranasal or intratracheal instillation produces in monkeys a pneumonic disease similar to that seen in man (see Bedson and Western 1930, Gordon 1930, Rivers and Berry 1931). For a description of the pathological lesions in man and animals, see Lillie (1933).

Ætiology.—The disease was first thought to be due to Nocard's bacillus—an organism apparently identical with *Salm. typhi-murium*—but later work showed

FIG. 298.

Intracellular colonies of psittacosis virus in rabbit cornea. From a tissue culture. On the right the colonies are situated outside the nucleus, which contains three nucleoli. On the left the colony is lying over the nucleus, but is not inside it. (× 1500.)

(From photograph kindly supplied by Dr. Robinow.)

that it was caused by a virus or a virus-like body. Bedson and his colleagues have been largely responsible for the ætiological investigation of the disease (Bedson *et al.* 1930, Bedson and Western 1930, Bedson 1932, 1936, Bedson and Bland 1932, 1934). They established the infectivity of human blood; they transmitted the infection to budgerigars and mice; they demonstrated the presence of virus-like bodies in infected tissues; they grew these bodies in tissue culture; and they showed that they were specifically agglutinated by psittacosis antiserum, and that they contained two different antigens, one heat-labile and one heat-stable, both of which were demonstrable by the complement-fixation reaction. Microscopical examination of suitable infective material, such as the tissues of mice suffering from the disease, reveals the presence of minute coccal and bacillary bodies, arranged singly and in pairs, and bearing a resemblance to rickettsiæ and to Paschen granules. They were described almost simultaneously by Levinthal (1930) in Germany, Coles (1930) in England, and Lillie (1930) in the United States, and are therefore sometimes referred to as L.C.L. bodies. They can be stained

with Giemsa, and better still with River's modification of Castaneda's rickettsial stain. They can be thrown down almost completely by centrifugation at 5,000 r.p.m. for 2 hours. They are largely held back by a Berkefeld N, a Chamberland L2, or a Seitz EK filter, but go through a gradocol membrane having an average pore diameter of 0·6 μ. Their probable size is about 200–300 mμ (Levinthal 1935, Lazarus *et al.* 1937). In tissue culture they increase rapidly in size, become embedded in a homogeneous ground substance, and are later replaced by smaller bodies (see Bland and Canti 1935). They can be cultivated on the chorio-allantoic membrane of the developing chick embryo for months without loss of virulence for mice, and can be consistently recovered from the spleen and liver of the embryo, which usually dies in 3–4 days (Burnet and Rountree 1935, Lazarus and Meyer 1939). They cannot be grown in the absence of living cells, nor do they appear able to grow extracellularly in tissue cultures (MacCallum 1936). They survive in frozen mouse spleen for 2 months, but die out rapidly in 50 per cent. glycerol phosphate at 6° C. Injected into guinea-pigs, they give rise to the production of agglutinins. The nature of these bodies is still in doubt, but in their general characteristics they would appear, as already pointed out, to be intermediate between the rickettsiæ and the filtrable viruses.

Owing to minor differences in pathogenicity of virus strains isolated from different avian hosts, Meyer, Eddie and Yanamura (1942) have suggested that the term psittacosis should be reserved for human infections contracted from psittacine birds, and the term ornithosis used for infections from petrels, pigeons and chickens. The wisdom of such a suggestion is open to doubt. If the practice should become established of coining a special name for the disease caused by every antigenic or pathogenic variant of an organism, then the whole nomenclature of the bacterial and virus infections will have to be revised.

Diagnosis and Immunity.—A rapid diagnostic test for the human disease, consisting of intraperitoneal injection of the patient's sputum into mice and the subsequent demonstration of elementary bodies in impression smears from the liver and spleen, has been described by Rivers and Berry (1935). The virus may be present in the patient's blood during the first four days of illness. The serum of convalescent patients contains complement-fixing bodies, but has little neutralizing power (Bedson 1933). Post-mortem material should consist of portions of pneumonic lung, any pleural or pericardial effusion, the liver, and the spleen. Suspensions, lightly centrifuged or passed through a coarse filter, should be injected intraperitoneally into mice; negative results, however, are common. The demonstration of virus in suspected birds is best accomplished by direct microscopical examination and by mouse inoculation (see Report 1937).

Vaccination experiments are still in the early stage. Bedson (1933, 1938) has been able to immunize mice by inoculation with a 0·1 per cent. formolized vaccine, in which no living virus could be demonstrated. Protection is not complete, even against small doses; infection almost invariably results, but remains latent—often for several months. Specific neutralizing bodies appear in very low titre in the blood of the vaccinated animals (see also Rivers and Schwentker 1934, Yanamura and Meyer 1942). According to Heilman and Herrell (1944), penicillin is of value in treatment of the experimental disease in mice, but it is doubtful whether it is similarly effective in human beings. For a general description of the disease and investigations on it, see also Sturdee and Scott (1930), Branham *et al.* (1930), Rivers (1934), Lazarus and Meyer (1939), Enders (1914).

Pacheco and Bier (1930), it may be noted (for further references, see Rivers and Schwentker 1932), described a disease of parrots in Brazil which closely resembled psittacosis in its clinical picture and in the macroscopic focal areas of necrosis found in the liver at post mortem, but which differed from psittacosis in certain respects. Thus, infection was confined to birds of the parrot family; it could not be transmitted to other laboratory animals; man appeared to be insusceptible; the virus passed readily through Berkefeld N and Chamberland B candles; and the parasitized cells contained acidophilic intranuclear inclusions. These observations were confirmed by Rivers and Schwentker (1932), who regarded the disease as undoubtedly different from psittacosis.

Smadel, Jackson and Harman (1945) have reported the isolation of a new virus from army pigeons suffering from an epizootic disease. It was usually associated with the psittacosis virus, but was occasionally found alone. It differed from the psittacosis virus in its smaller size, its more rapid growth on the chorio-allantoic membrane, its greater resistance to storage at — 20° C., its ability to give rise in the parenchymatous tissues of the liver to intranuclear inclusion bodies of the herpetic type, and its lack of pathogenicity for rabbits, guinea-pigs or mice. It is referred to as the I.N.I. (intranuclear inclusion) agent. Whether it is related to the virus producing intranuclear inclusions in parrots is doubtful.

VIRUS PNEUMONIAS OF MAN AND ANIMALS

A study of primary pneumonia during the past few years has revealed a considerable, and apparently increasing, proportion of cases that cannot be ascribed to infection with known bacteria. The majority of these cases have been characterized by a relatively mild illness of insidious origin, widespread lesions in the lungs as revealed by X-ray examination, a fairly prolonged course, absence of leucocytosis, insusceptibility to sulphonamide treatment, and a very low case mortality (see Francis 1944). Epidemiological studies by Dingle and his colleagues (1943, 1944) at Camp Claiborne, Louisiana, suggest that the disease has a fairly long incubation period—2 to 3 weeks—that it does not spread readily by contact, that it has no marked seasonal incidence, and that in all probability the pneumonic lesions represent merely a complication of a widespread respiratory infection, in much the same way as meningitis is sometimes superimposed on a basic epidemic of meningococcal rhinopharyngitis. On the other hand, groups of cases have been described by Reimann (1938) and others in which the disease has been very much more severe.

The ætiology of these pneumonias is still in doubt. Besides the rickettsiæ of Q fever (see p. 1850) several well-known viruses, such as the influenza virus, the psittacosis virus, the lymphocytic choriomeningitis virus, and the measles virus may give rise to pneumonia, but in many cases of the type of pneumonia we are now considering none of these viruses has been demonstrated. Numerous workers, however, have reported the isolation of viruses of one sort or another from human pneumonia patients; but it is as yet too early to form any clear picture of the relation of these viruses to each other or to the part they play in the causation of pneumonia in man and animals. Investigators have suffered from the necessity of using animals for purposes of isolation, rendering it impossible to tell whether the virus so obtained was derived from the patient or from a latently infected animal whose infection had been stimulated to activity by the introduction of

foreign non-specific material. It seems probable that more than one type of virus is concerned in the production of pneumonia, and that more than one type of clinical disease in man will eventually be defined. On this assumption we shall refer to this group of diseases as the " virus pneumonias," in preference to the common term " atypical pneumonias," which is either meaningless or misleading. Brief mention may be made of some of the more important viruses that have been isolated.

The *meningo-pneumonitis* virus was isolated repeatedly by Francis and Magill (1938) from ferrets that had been inoculated with throat washings of human patients suffering from an epidemic influenza-like disease. Whether it was derived from the patients or from the ferrets it was impossible to say. The virus passed through a Berkefeld V but not an N candle, and through a gradocol membrane of 430 $m\mu$ A.P.D., but not through one of 250 $m\mu$. It grew readily on the chorio-allantoic membrane of the developing chick embryo, but not in chick-embryo Tyrode tissue cultures. It was pathogenic for ferrets and mice by intranasal, subcutaneous, and intraperitoneal inoculation, and for monkeys, rabbits, and guinea-pigs by subcutaneous or intraperitoneal, but not by intranasal, inoculation. Intranasal inoculation of ferrets and mice was followed by pulmonary consolidation, from which the ferrets recovered and the mice usually died. Intracerebral inoculation of mice caused paralysis and death in 2 to 10 days, according to the dose.

Weir and Horsfall (1940) isolated a virus from pneumonia patients by intranasal inoculation of throat washings into the *wild mongoose* (*Herpestes griseus*). The virus passed through a Berkefeld N candle; it grew on the chorio-allantoic membrane of the developing chick embryo; it gave rise to pulmonary consolidation in the mongoose; it passed from mongoose to mongoose by contact; it was non-pathogenic for ordinary laboratory animals, including the ferret; and it was neutralized by sera of human patients convalescent from pneumonia.

Horsfall and Hahn (1940) demonstrated the presence of a virus—known as the *mouse pneumonia virus*—in normal mice. Under ordinary conditions it appeared to be avirulent, but by serial passage through mice, inoculated intranasally with infective lung, it became capable of causing a fatal disease characterized by pulmonary consolidation. The virus was about 100–150 $m\mu$ in diameter; it could be grown in chick-embryo Tyrode tissue culture medium; it was non-pathogenic to other laboratory animals; it was pathogenic to mice only after intranasal inoculation; and it was neutralized by about 30 per cent. of normal human sera.

Eaton, Beck and Pearson (1941) isolated a virus from four cases of pneumonia. It proved virulent for mice by intranasal or intracerebral inoculation, but not by intraperitoneal inoculation. It did not pass through a Berkefeld V candle, and it appeared to be closely related to the meningo-pneumonitis virus, though not apparently identical with it antigenically (Beck and Eaton 1942). Elementary bodies were demonstrable in impression smears from infected organs.

Gönnert (1941) described a virus found in the lungs of normal mice. It proved highly virulent after intranasal mouse passage, giving rise to broncho-pneumonia. In the tissues inclusion bodies were numerous. Elementary bodies were visible in large numbers, particularly in the leucocytes. The virus, which is referred to as the *broncho-pneumonia virus*, apparently passed through coarse filters, and bore a close resemblance to the viruses of lymphogranuloma, psittacosis and trachoma.

Nigg and Eaton (1944) described a pneumotropic virus met with in normal mice. It proved highly virulent on intranasal inoculation, giving rise in small doses to focal lesions in the lungs, and in large doses to extensive consolidation. In the earliest stages of infection elementary bodies could be demonstrated in the large mononuclear cells. The virus had no affinity for the nervous system. It could be cultivated in the yolk sac of the developing chick embryo. It was pathogenic to mice and hamsters, but not to rabbits. By complement-fixation and cross-immunity tests it could be distinguished from other

mouse pneumonia and meningo-pneumonitis viruses. According to Rake Shaffer, and Thygeson (1942) it is susceptible to sulphonamides.

Eaton, Meiklejohn, and van Herick (1944) were able to demonstrate a virus, derived from human pneumonia patients, by intranasal inoculation of cotton rats (*Sigmodon hispidus*). Pulmonary consolidation was produced, and the virus could be carried over by serial passage. It could be adapted to grow in the developing chick embryo. No elementary bodies were found in infected tissue, and the virus proved non-pathogenic to other laboratory animals. The virus was neutralized by the sera of human convalescents. Owing to the absence of demonstrable elementary bodies in the tissues, it is doubtful whether this virus should be included in the lymphogranuloma-psittacosis group.

Other viruses from human pneumonia patients have been described by Stokes, Kenney and Shaw (1939), Rose and Molloy (1943) and Karr (1943).

The relation of these viruses to each other is still under discussion. Complement-fixation, cross-immunity, and animal pathogenicity tests suggest that some of them, at least, are closely allied to the lymphogranuloma and the psittacosis viruses, and that with these they form a group analogous to that of the animal-pox or the pleuropneumonia viruses (see Rake, Eaton and Shaffer 1941, Eaton, Martin and Beck 1942, Pinkerton and Moragues 1942, Horsfall *et al.* 1943).

In some cases of virus pneumonia, "*cold*" *agglutinins*, i.e. agglutinins acting on human red corpuscles at 0° C. but not at 37° C., can be demonstrated in fairly high titre and may be of value in diagnosis (Turner 1943, Turner *et al.* 1943, Peterson *et al.* 1943, Horstmann and Tatlock 1943); though it must be remembered that they may occur in other diseases such as paroxysmal hæmoglobinuria, tropical eosinophilia and trypanosomiasis (see Viswanathan and Natarajan 1945). For references to papers on virus pneumonia in man, the reader should consult an article by Dingle and Finland (1942).

Cat Distemper

A disease, known variously as distemper, nasal catarrh, or influenza, has been studied to a limited extent in the cat (Hindle and Findlay 1933, Dalling 1932, 1934, Baker 1942, 1944). It appears to be caused by a virus entirely different from that infecting dogs. The disease is highly infectious, debilitating, and lasts about a month. It is characterized by sneezing and coughing, and a mucopurulent discharge from the eyes and nose. Pneumonia is not usually detectable during life, but if the animal is killed, greyish densely consolidated areas are found in the anterior lobes of the lungs. The disease can be reproduced in cats by intranasal infection with ground-up pneumonic lung; parenteral inoculation causes only a mild fever. Mice injected intranasally die in 3-5 days, and after serial passage of virus in 2–3 days. Infection can be transmitted to rabbits, guinea-pigs, and hamsters as well by intranasal inoculation, but only mice and hamsters die. Films from the lungs of these animals show dense plaques and aggregations of elementary bodies similar to those seen in psittacosis. The virus appears to be fairly large, as it does not pass Berkefeld N candles, except in very small amount. It can be grown in the yolk sac of the developing chick embryo. It is killed at 50° C. in 30 minutes. In 50 per cent. glycerol it is inactivated within about a month. The serum of convalescent cats contains specific complement-fixing bodies.

Baker's virus is similar in many respects to the virus of mouse pneumonia described by Nigg (1942). Thomas and Kolb (1943), who have compared the

two, find that they are related antigenically, not only to each other, but to the virus of psittacosis. According to Hamre and Rake (1944), Baker's feline pneumonitis virus differs from the meningo-pneumonitis virus (see p. 1876) in the nature of its toxin and corresponding antitoxin, and in the larger dose required to set up infection in mice by intracerebral inoculation.

Another virus isolated from feline pneumonia, but differing from Baker's virus, was described by Blake, Howard and Tatlock (1942). It may be noted that cases of pneumonia in human patients and in cats have not uncommonly been associated, though there is yet no definite evidence to show that the same virus was responsible for both.

TRACHOMA

Since Noguchi (1927, 1928) described the isolation of a very small Gram-negative bacillus, *Bact. granulosis* (see p. 901) from 4 out of 5 American Indians suffering from trachoma, extensive investigations on the ætiological significance of this organism have been carried out in different parts of the world, and a voluminous literature has sprung up.

Noguchi found that the inoculation of pure cultures of this bacillus beneath the conjunctiva and on to the scarified conjunctiva of *rhesus* monkeys was followed in 2 to 4 weeks by a granular conjunctivitis, which slowly progressed till after 2 to 5 months the inoculated conjunctiva closely resembled the human trachomatous conjunctiva in the early stages of the disease. The lesions were follicular; they extended over the tarsus, which became thickened; and in one monkey definite scar formation occurred. Histologically the lesions were closely similar to those found in human trachoma. The disease could be passed in series from monkey to monkey, and the organism could be recovered from the experimental lesions produced. The organism had no effect when inoculated into the conjunctiva of the rabbit.

Attempts to confirm Noguchi's findings have met with a varied degree of success. Olitsky (1930) and Olitsky, Knutti and Tyler (1931*a*, *b*, *c*) claim to have succeeded in isolating *Bact. granulosis* from natural trachoma in human beings and from monkeys infected with human trachomatous material, and to have conveyed the disease to *rhesus* monkeys by conjunctival inoculation with pure cultures of this organism. On the other hand, several workers including Wilson (1931) in Egypt, Bengtson (1932) in the United States, Schuurman (1932) in Java, and Tang and Chou (1935) in China have failed to isolate this organism during the investigation of large numbers of cases.

Two factors contribute to this confusion. The first is the varying definition of trachoma adopted by different workers: the second is the spontaneous occurrence in monkeys of a follicular conjunctivitis simulating in some respects trachoma in human beings (see Wilson 1928, Olitsky and Tyler 1933, Olitsky, Syverton and Tyler 1933). Trachoma is a chronic disease progressing from early conjunctival inflammation to late hypertrophy and cicatricial changes. According to Bland (1944*a*), the four characteristic signs are: (1) inclusion bodies—described as " Lindner's initial bodies " and " von Prowazek-Halberstaedter inclusion bodies " (see Bengtson 1928)—in conjunctival epithelial scrapings; (2) follicular reaction in the tarsus as well as in the fornices; (3) invasion of the cornea by blood vessels; and (4) subsequent scarring of the conjunctiva. Bland has found that grivet monkeys (*Lasiopyga griseoviridis*: syn. *Cercopithecus æthiops*) and vervet monkeys

(*Lasiopyga pygerythra*: syn. *Cercopithecus pygerythra*), both of which suffer from spontaneous folliculosis, can be infected with trachoma—as shown by subsequent inoculation of human volunteers—but that the trachomatous reaction cannot be distinguished clinically or histologically from folliculosis. These animals are therefore useless for most experimental purposes. Baboons (*Papio hamadryas*) are likewise prone to develop spontaneous folliculosis (Bland 1944*b*). On the whole, Bland (1944*c*) seems to regard *Macacus rhesus* as the most reliable experimental animal, though only about 50 per cent. of the animals are susceptible to trachoma.

Some workers, notably Busacca (1933, 1937) and Cuénod and Nataf (1936, 1937, 1938), regard the disease as a rickettsial infection.

Microscopical examination reveals the presence of tiny coccoid bodies, 0·2–0·3 μ in diameter, staining pale blue with May-Grünwald-Giemsa, occurring sometimes in enormous numbers in epithelial cells removed by gentle scraping from the conjunctiva. The name *Rickettsia trachomatis* has been suggested for them (Foley and Parrot 1937). The organism is said to have been cultivated in the louse's intestine and then to have reproduced the disease in monkeys and in a blind human eye. In addition numerous workers have reported a positive Weil-Felix reaction in trachoma, particularly in the acute stages. None of this evidence is entirely convincing. The occurrence of epithelial cell inclusions is equally compatible with a virus origin. The cultivation of rickettsiæ in the louse's intestine has not been confirmed by workers like Weigl (1939) and Trapesontzewa (1939), who took the precaution to work with lice free from *Rickettsia rocha-limæ*. Durand and Lumbroso (1938) in Tunis found, in contradistinction to Poleff and Nain (1938*a*, *b*) in Morocco, that control patients gave a Weil-Felix reaction almost as often as trachomatous patients. Moreover Kirk, McKelvie and Drysdale (1939), working in the Northern Sudan where typhus is absent, examined 200 sera from patients in different stages of trachoma, but failed to find a single one that agglutinated *Proteus OX* 2 or *Proteus OX* 19 above 1/25.

More recently, the conviction has been growing that the disease is of virus origin.

Julianelle, Harrison and Morris (1937) were able to confirm a previous observation of Nicolle and Cuénod (1921), namely that the infective agent remains alive for several days in the rabbit's testicle—an observation that may be utilized for freeing trachomatous material from contaminating bacteria. It does not, however, survive testicular passage. Filtration experiments were unsatisfactory; in nine attempts to filter the infective agent through a Berkefeld V candle or a collodion membrane of 0·6 μ A.P.D. the results were uniformly negative. Tissue cultures were likewise unsuccessful. The agent was found to survive in the ice-chest for 2 or 3 days as a rule, but exposure to a temperature of 45°–50° C. or to 25 per cent. bile at 37° C. inactivated it in 15 minutes. Thygeson (1934*a*) claims to have demonstrated the presence of elementary bodies, about 0·25 μ in diameter, in trachoma, and to have filtered them successfully through a collodion filter of 0·6–0·75 μ A.P.D. Rake, Shaffer and Thygeson (1942) have shown that the serum of trachomatous patients can fix complement in the presence of a lymphogranuloma antigen, suggesting that the infective agent of trachoma is related to that of lymphogranuloma inguinale. Likewise both organisms are reported to be susceptible to sulphonamides.

Julianelle (1938), who has reviewed the whole evidence in a monograph that should be consulted by those desirous of further information, sums up the known properties of the infective agent of trachoma as follows: low infectivity, even for man; occasional filtrability; high degree of tissue specialization; poor antigenicity; inability to grow in tissue culture; sensitivity to deleterious agents; and power of production of inclusion bodies in the invaded tissues. All these

properties suggest that the causative agent is a virus. The final proof of this conclusion is still awaited.

Though trachoma is said to be favourably influenced by treatment with the sulphonamides, it is very doubtful whether these drugs have any direct action on the virus. Such improvement as is observed seems to be more probably due to their influence on secondarily infecting agents (see Lavery 1945). It may be added that Bernasconi (1941, 1943) brings evidence to suggest that nutritional deficiency plays an important aetiological rôle and that the disease can be cured by the addition of Vitamins A and D to the diet.

Inclusion Blennorrhœa

Inclusion blennorrhœa is a disease that attacks the eyes of new-born infants and of adults. Though it closely resembles trachoma in many respects, the balance of evidence seems to be against the identity of the two diseases. The name inclusion blennorrhœa was coined by Linder (1911), who distinguished the disease in the new-born from gonorrhœal ophthalmia. According to Thygeson (1934*b*) and Thygeson and Mengert (1936), whose papers the reader should consult for references to the observations of previous workers, the onset of the disease in infants is 5 to 9 days after birth. It is characterized by the presence in some of the conjunctival epithelial cells of cytoplasmic inclusion bodies indistinguishable from those of trachoma, by its acute onset, its failure to produce destructive lesions of the cornea, its long duration—3 to 12 months—and its resistance to treatment. In adults the disease is sometimes referred to as *swimming bath conjunctivitis*, though it is clear that such a term includes common infections due to bacteria such as the Koch-Weeks bacillus as well as the disease we are now considering (see Julianelle 1938). The observations of Thygeson and of Julianelle, Harrison and Lange (1938) show that inclusion blennorrhœa can be transferred to monkeys, especially baboons, and that, in contrast to experimental trachoma, inclusion bodies can be demonstrated in the conjunctiva of the inoculated animals. Elementary bodies about 0·25 μ in diameter are found in infective material; they can just pass a collodion filter of 0·7 μ A.P.D. Tissue cultures have so far been unsuccessful. The disease does not seem to be highly contagious. There is evidence that it affects primarily the genital tract, and that the eye is infected by contamination with material from this source. Like trachoma, it is said to be susceptible to sulphonamides (Rake *et al.* 1942), but this is doubtful.

It may be mentioned that the disease *Heartwater of cattle* is sometimes included in this group, but as the evidence is not entirely conclusive, we have considered it best to leave it in the rickettsial diseases (see p. 1862).

CHAPTER 86

FILTRABLE VIRUS DISEASES—*Continued*

B. GROUP CHARACTERIZED BY LESIONS OF THE SKIN

VARIOLA AND VACCINIA

Variola, or smallpox, is a disease of great antiquity, of widespread distribution, affecting both sexes at all ages, and occurring both endemically and epidemically. According to Rajchman (1928) there were over 300,000 cases of the disease in the world in 1927; in India alone it causes about 50,000 deaths annually. In recent years, however, smallpox has been characterized by an almost universal decrease in the case-mortality rate. There seems little doubt that this is due largely to the occurrence in many localities of a mild type of disease, usually referred to as "variola minor" or "alastrim." There are in fact two entirely distinct types of the disease: (1) the classical type, variola major, with severe symptoms and a case-mortality rate of 10–30 per cent.: (2) the mild type, variola minor or alastrim, with mild symptoms and a case-mortality rate of only 0·1–0·3 per cent. In some countries the two types may coexist side by side; thus in 1922 there was an epidemic of the mild type in the Midlands and North of England, in which 895 cases were reported with only 3 deaths—a case-mortality rate of 0·3 per cent.—and a smaller epidemic of the classical type in London, in which 78 cases were reported with 24 deaths—a case mortality of 31 per cent. (see also Report 1938). In the United States the number of reported cases fell from 42,679 in 1930 to 4,346 in 1934—apparently as the result either of the replacement of variola major by alastrim, or of the widespread immunization of the population against variola major by unrecognized infections with alastrim (see Russell 1941). Whether alastrim is, as the name variola minor implies, merely a mild form of smallpox or a separate disease is still in doubt (see p. 1889).

The mode of infection in smallpox is not clear. It used to be thought that infection occurred from the inoculation of the skin with dried pustules and scabs, but this is now believed to be an unusual method. Epidemiological and experimental evidence points to infection by the nasopharyngeal route. The observations which indicate that infection is not usually carried by dried pustules and scabs are: (1) cases of smallpox occur without a rash which nevertheless prove infectious; (2) experimental inoculation of the skin with variola seldom leads to more than a mild disease with imperfectly developed pocks. On the other hand, the virus is said to be generally present in the nasopharynx of patients, and to be sometimes demonstrable in this situation even during the incubation period. Von Wasielewski and Winkler (1925), who review the evidence, conclude that the virus is coughed out in droplets, and gives rise to infection of the mucosa of the upper respiratory

tract; from the infected mucosa the virus is then distributed to all parts of the body.

That variola is primarily caused by a filtrable virus, there is no doubt. Filtration experiments are not, however, always successful, probably because of the imperfect liberation of the virus from the cells, or its adsorption by particulate matter in the suspension (see Green and Eagles 1931). During the disease the virus appears to be widely distributed throughout the body; it has been demonstrated in the blood stream (Ohtawara 1922, Parker and Nye 1925*a*, von Wasielewski and Winkler 1925, Haagen 1928). Though Levaditi (1924) maintains that the chief manifestations of the disease result from an affinity of the virus for the skin, there is now little doubt that the primary action of the virus is on the mesoderm; for this reason it is sometimes referred to as "viscerotropic" (see Ledingham 1924, Hurst 1936).

The cultivation of the virus of variola, and of the closely associated vaccinia virus, in the rabbit's testicle, in tissue cultures *in vitro*, and on the chorioallantoic membrane of the developing chick embryo, has already been described (Chapter 41).

Animal Inoculation.—Smallpox cannot be reproduced in its typical form in any of the lower animals. In calves and rabbits only minimal lesions are produced; and if material from these lesions is passed continuously through a series of animals, the virus is so altered that it gives rise to vaccinia or cow-pox, and reproduces this type of infection when again inoculated into a child.

The most susceptible animal to *variola* is the *monkey*. Intracutaneous inoculation of pus from a human patient gives rise to a papule after 5 days; by the 8th day this is vesicular, and by the 10th day a typical pock is formed, with a raised congested edge surrounding a crateriform depression, partly filled with dark purulent material (Blaxall 1923, Gordon 1925). Intratesticular inoculation of the monkey with variola virus gives rise to an orchitis with the appearance of a rash on the scrotum. Passage from one monkey to another is almost uniformly successful. Cats and dogs are said to be less susceptible than monkeys, but more so than rabbits. Infection in the less susceptible animals may be of the "inapparent" type, in which immunity develops in the absence of any clinical manifestations of disease (Teissier *et al.* 1931). Pus from cases of alastrim gives rise to very much the same lesions as that from the classical type of smallpox.

Both calves and rabbits can be readily infected with *vaccinia*. Inoculation of the scarified skin of a *rabbit* with calf lymph causes a red swelling on the 3rd day, which increases until a red papule is formed, surrounded by a red areola; the papules become vesiculated about the 5th day, and tend to coalesce and to become pustular; scabbing follows on the 7th or 8th day. A good calf lymph should give a reaction in the rabbit when diluted 1/1000; sometimes a reaction occurs even in a 1/100,000 dilution. If vaccine lymph is inoculated intravenously into a rabbit, and a portion of the skin is thereafter shaved, vaccinial papules appear about the 3rd day on the shaved area (Calmette and Guérin 1901). In poorly nourished and in nursling rabbits the susceptibility of the skin to infection is said to be decreased (Sprunt 1942, Pearce *et al.* 1936). If a very large dose of vaccine lymph is inoculated intravenously into a rabbit—1 to 2 ml. of undiluted stock emulsion—or a highly virulent virus is employed, a generalized eruption occurs over the entire body surface, and lesions may develop in the internal organs (Noguchi 1918, Douglas *et al.* 1929, Armstrong and Lillie 1929). Subcutaneous inoculation may give rise to a local pustular eruption, but often no superficial lesion appears at all. Intratesticular inoculation results in the development of an orchitis and œdema of the scrotum; the animal dies about the 6th day. Inoculation on the scarified cornea gives rise to a keratitis and purulent conjunctivitis. Intracerebral inoculation of rabbits is followed

by trembling, paralytic, and other nervous symptoms and by death on the 5th to the 8th day; the brain and spinal cord of these animals prove infective to fresh rabbits, when inoculated on to the cornea or intracerebrally (Marie 1920). After intranasal inoculation, the virus can be demonstrated in the cervical lymph glands in about 12 hours; it appears to become attached to the lymphocytes and hence finds its way into the blood stream (Yoffey and Sullivan 1939).

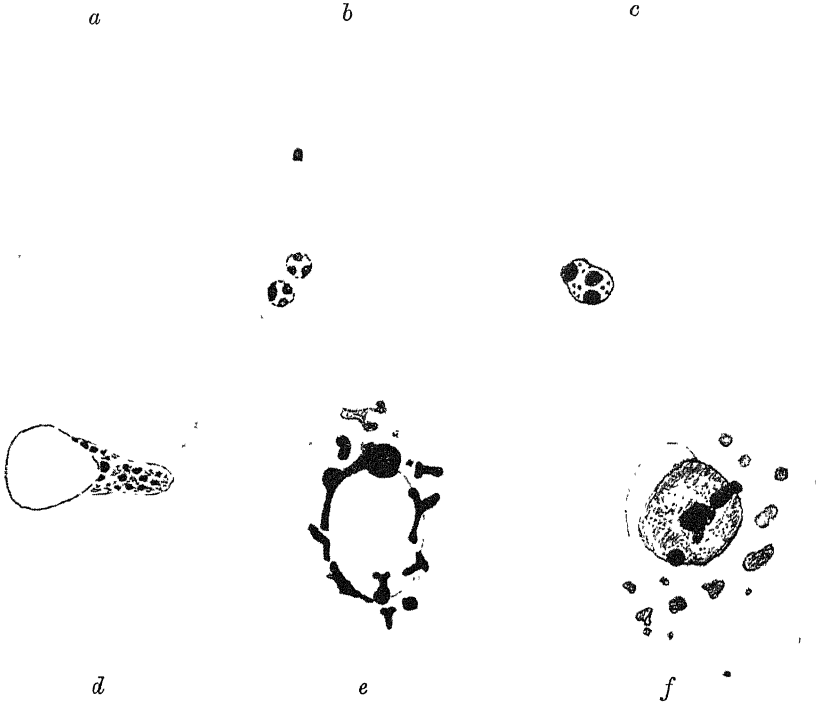

FIG. 299.

c = cell 2 days after inoculation, containing a solitary vaccine body in which large and small droplets may be distinguished.
d = cell 4 days after inoculation, showing a vaccine body partly surrounding the nucleus.
e = cell 5 days after inoculation, showing vaccine bodies surrounding the nucleus.
f = cell 5 days after inoculation, containing numerous vaccine bodies.

(After Cowdry 1927.)

In *mice* a vesiculo-pustular reaction may often be obtained by inoculation of the scarified foot pad or tail with vaccinia virus (Rosenau and Andervont 1931).

Histologically, the main lesion in the rabbit inoculated intracutaneously is a diffuse perivascular infiltration of the dermis; the changes in the epidermis appear to be secondary to this. According to Ledingham (1924) the vaccinial lesion is essentially an acute infective granuloma in which the reticulo-endothelial system is primarily and dominantly involved. By continued passage through the brain of rabbits, the virus may acquire more or less fixed properties—like the virus of rabies—causing death regularly in 5 to 8 days (Marie 1920). To this fixed virus the term "neurovaccine" is applied

by Levaditi and Nicolau (1923). The virus, though having a special affinity for the nervous tissue, is still able to produce typical lesions on cutaneous inoculation.

Guarnieri Corpuscles and Elementary Bodies.—As long ago as 1892 Guarnieri (1894) observed in the lesions of variola and of vaccinia peculiar intracellular bodies, which he regarded as being of protozoal nature. When stained by methylene blue, the body shows a slightly stained spherical mass lying eccentrically, and surrounded by a clear area, which in its turn is encircled by a number of small granules. These Guarnieri corpuscles may be produced very rapidly—in a few hours—by inoculation of the scarified cornea of a rabbit with the vaccinia virus. Fixed, and stained with methylene blue and eosin, they appear as irregular pink and lilac masses, which indent the nuclei, and which may contain acidophilic or basophilic granules (Figs. 299, 300). Besides the Guarnieri corpuscles, which are always present at some stage in variolous and vaccinial lesions, very tiny intracellular bodies, 0·1–0·25 μ in diameter, have been described ; they are generally called "Paschen's granules" (see Fig. 232, p. 953). The work of Ledingham and his colleagues, of Paschen, and of others (see Chapter 41) leaves no doubt that the Paschen granules, or elementary bodies as they are often called, constitute the actual causative virus of the disease. The Guarnieri corpuscles probably represent intracellular microcolonies of the virus. The microscopical demonstration of the virus particles *in situ* may be accomplished by suitable staining methods (see Taniguchi *et al.* 1932*a*, Haagen and Kodama 1934, Herzberg 1934, 1936, Tang and Wei 1937). For a description of the general properties of vaccinial elementary bodies, the reader is referred to the review by Smadel and Hoagland (1942).

(After Ewing.)

Laboratory Diagnosis of Smallpox.—The antigenic structure of the vaccinia virus has already been considered in Chapter 41. The serological diagnosis of smallpox is made by mixing a suspension of ground-up variolous material with

an antivaccinial rabbit serum, and incubating at 37° C. A positive reaction is marked by the appearance of a finely floccular precipitate, similar to that obtained with vaccinial material (Gordon 1925). Using this method, Tulloch (1928) was able to make a rapid diagnosis of smallpox during the course of an epidemic in Dundee. Since then, the value of the flocculation test has become increasingly obvious. The careful studies of Burgess, Craigie and Tulloch (1929) and Craigie and Tulloch (1931) show that it constitutes an important practical method in the rapid diagnosis of doubtful cases of smallpox. For a description of the detailed technique reference should be made to the report by Craigie and Tulloch (1931). The serum of patients suffering from variola may also agglutinate suspensions of elementary bodies (Amies 1932). The reaction appears to be specific for variola and vaccinia. Some discussion has arisen over its real nature, but it is probably a mixed precipitation and agglutination reaction (see Craigie 1932, Gordon 1935*a*, *b*, Ledingham 1935*a*, and Chapter 41). Diagnosis may also be made by the complement-fixation test using a suspension of crusts or of vesicular fluid as antigen. According to Craigie and Wishart (1936) this test is 8–10 times as sensitive as the flocculation test. More recently van Rooyen and Illingworth (1944) have recommended the direct microscopical examination of suitably stained smear preparations from scrapings of papules or vesicles. The elementary bodies, of variola and vaccinia are said to be larger, more numerous, and to stain deeper than those of varicella.

Tests depending on animal inoculation are less satisfactory. McKinnon and Defries (1928) and Defries and McKinnon (1928) find that the intracutaneous inoculation of variolous material into rabbits produces a reaction characterized by a red palpable swelling, commencing on the 2nd day and reaching its maximum about the 4th day, when it appears as a firm, elevated plateau, 10–20 mm. in diameter; subsequently the central red area becomes straw-coloured, and desquamation or crust formation may occur; the lesion disappears by the 12th day, leaving no scar. On the other hand, if the variolous matter is injected into vaccinated rabbits, either no reaction occurs at all, or there is an allergic reaction, characterized by the rapid appearance and disappearance of a red tense nodule (Blaxall 1923). Material from varicella, as a rule, gives rise to no reaction in either normal or vaccinated rabbits, though on this point the evidence is conflicting (Hull and Nauss 1926). Paul's test, which consists in the production of a keratitis by inoculation of the rabbit's cornea with variolous material, is sometimes used in diagnosis, but according to Defries and McKinnon (1928) it is positive in only 50 per cent. of cases. By inoculating pustular fluid on to the chorio-allantoic membrane of the developing chick embryo, and examining for pocks after 2–4 days' incubation at 35°–36° C., a positive diagnosis may sometimes be made (Bohls and Irons 1942); but owing to non-specific reactions and other pitfalls this method should be used with caution.

Immunity.

Our whole knowledge of immunity may be said to have started with Jenner's discovery in 1796 that inoculation with cow-pox protects against subsequent inoculation with smallpox. He believed that cow-pox was really smallpox, modified by passage through the cow—a belief to which investigations of recent years have lent considerable support. Cutaneous inoculation of the calf with variolous material from man produces insignificant lesions; but if the material from these lesions is passed through further calves in series, then after three or more passages a good vesiculo-pustular eruption appears on the inoculated skin. This experimentally produced disease is apparently identical with the naturally occurring cow-pox. If the pustules are scraped at the height of their develop-

ment, ground up in a mortar, and mixed with glycerolated saline, the resulting product is indistinguishable from vaccine lymph. In practice it is found beneficial to pass the vaccinia virus from the calf to a rabbit, from the rabbit to a calf, from the calf to a child, and from the child back to a calf, or through some similar series; in this way the activity of the virus seems to be better maintained than by continuous passage through one species of host.

Experimentally, rabbits that have been inoculated with vaccinia virus, either cutaneously, subcutaneously, or intravenously, become resistant to a second inoculation within about 10 days. If repeated injections are given, the rabbits become hyperimmunized, and in their serum neutralizing viricidal antibodies can be demonstrated, as well as agglutinins, precipitins, and complement-fixing bodies (Ledingham 1924, Gordon 1925, Sobernheim 1925). W. Smith (1929) has brought evidence to show that, in rabbits inoculated intravenously, the virus is rapidly taken up by the formed elements of the blood—probably the leucocytes—and remains in the circulation for at least 8 days. (See also Douglas and Smith 1930, Gildemeister and Hilgers 1930.) In order to demonstrate its presence, it is necessary, however, to fractionate the blood, and use only the washed cells for injection. If the whole blood is injected, the presence of the virus is masked by the antibodies, which become demonstrable in the plasma about the second day after infection, and increase up to the 6th or 7th day. This method of demonstrating the virus in material which, when injected in the original state, proves to be non-infective, may have an important bearing on future investigations into the distribution of the filtrable viruses within the body. (See also p. 1233.)

By whatever route the virus is introduced, provided an active strain is used, a general immunity develops. There is a partial exception to this in the cornea; a vaccinial keratitis renders the affected cornea resistant to further inoculation, but not necessarily the opposite cornea or the skin; similarly cutaneous vaccination, though rendering the skin refractory, may yet leave the cornea susceptible (Levaditi and Nicolau 1923). According to Sobernheim (1925) this statement must be modified; he brings evidence to show that after cutaneous inoculation the cornea does become immune to vaccinia, but the immunity develops more slowly in the cornea than in the skin—probably because of its poor blood supply. There seems little doubt, therefore, that immunity to vaccinia is a general and not a mere local immunity, and is dependent, to some extent at least, on the development of humoral antibodies.

Monkeys inoculated with vaccinia are completely protected against subsequent inoculation of variola (Gordon 1925); monkeys inoculated with variola or alastrim are either partly or completely protected against subsequent inoculation with vaccinia (Blaxall 1923, Gordon 1925). Immunologically the alastrim virus resembles the variola virus very closely, but minor differences are apparent in the degree of protection afforded by the different viruses against vaccinia. Generally speaking, vaccinia affords almost perfect protection against variola and alastrim, but the protection afforded by variola or alastrim against vaccinia is not so complete. It must be mentioned, however, that there is a type of mild smallpox in Australia which affords practically no immunity either to variola or vaccinia, and to which vaccinia or variola affords only incomplete protection (Ledingham 1925). The identity of alastrim with mild smallpox is open to question. Though cross-immunity between the two diseases suggests that they are caused by essentially the same virus (see Leake and Force 1927, Diem 1930), epidemiological evidence

does not wholly support this view (see Findlay 1936). Moreover, according to Torres (1936), the histological changes in the two diseases are distinctive. Findlay (1936) believes that smallpox and alastrim are caused by separate viruses, each of which breeds true, and each of which can give rise to vaccinia virus.

Again, the relation of vaccinia to variola, and of vaccinia to cow-pox is still in doubt. Most authorities agree that the vaccinia virus is a modified form of the variola virus. Nevertheless, by agglutination it can be shown that, though the two viruses possess a common antigen, they are not identical (Ledingham 1935*b*). It has been generally assumed, since the days of Jenner, that vaccinia is variola modified by passing through the calf, and that vaccinia is essentially the same disease as naturally occurring cow-pox. Downie (1939*a*, *b*), however, has pointed out that vaccinia and cow-pox viruses differ in their heat-labile antigens, and that they give rise to different lesions in animals; he would therefore regard the two viruses as being distinct.

Experiments in rabbits indicate that the highest immunity to vaccinia is produced by living virus. Gordon (1925) found that heat diminished the antigenic activity of the virus very considerably. Thus, to produce the same degree of protection as that afforded by raw virus, about 20 times as much virus heated to 55° C. for 30 minutes had to be employed; lymph heated to 65° C. had only 1/100 of the immunizing power of the 55° C. lymph, while lymph heated to 100° or 120° C. had practically no immunizing effect at all. According to Nakagawa (1924), lymph heated to 100° C. for 40 minutes still has some immunizing power, but very large doses have to be employed to demonstrate it. Virus treated by exposure to 1 per cent. phenol for 24 hours at 37° C. had much the same immunizing power as the 55° C. lymph.

There is no question that the antigenic power of heated, phenolized, or formolized vaccinia virus is very much less than that of the untreated virus. Its power of stimulating antibody production, especially protective antibodies, seems to be very slight, though it can still serve as an efficient hapten in the demonstration of skin sensitivity in a sensitized human subject or animal (see Kaiser 1929, Zehnder 1929, Bussel and Maysner 1930, Andervont and Rosenau 1930, Kraus 1931, Hilgers 1931, Craigie and Wishart 1933, Parker and Rivers 1936, Bernkopf and Kligler 1937). After vaccination of rabbits with raw lymph, immunity may be detectable about the 4th day; during the next 2 days it increases rapidly, and by the 10th day a substantial immunity is attained.

Prophylaxis and Human Vaccination.—It is scarcely necessary to describe here the prophylactic measures that should be taken on the discovery of a case of smallpox in a country in which it is normally non-endemic. They comprise the removal of the patient to an isolation hospital, disinfection of the patient's house, including steam disinfection of all infected clothing and bedding, daily supervision for 16 days of all contacts, vaccination or revaccination of contacts, and if thought desirable of the general population, exclusion of contacts from schools, factories and other places of congregation, and careful observation of all doubtful cases of disease.

Inoculated cutaneously into a fully susceptible human subject, vaccinia virus gives rise, after an incubation period of 3–4 days, to a papule, which on the 6th or 7th day becomes vesicular. The vesicle, which is multilocular, umbilicated, and surrounded by a red areola, progresses to the pustular stage between the 10th and 12th days, after which retrogression sets in and the pustule dries up. The crust becomes detached about the 21st day, leaving a red pitted scar—the

so-called foveation—which in the course of years turns white. The size of the reaction is dependent on the concentration of virus in the lymph (von Gröer 1935). A rise in temperature may occur about the 4th day, reaching its maximum about the 8th day; there may also be some enlargement and tenderness of the regional lymph nodes. A second inoculation made some years later may be followed by much the same reaction, or it may be accelerated—*vaccinoid reaction*—the papule appearing earlier and completing its evolutionary course in a shorter time. In persons recently vaccinated the so-called *immune reaction* is common; this consists of a papule that reaches its maximum size in 8 to 72 hours, and disappears without passing through the vesicular or pustular stage. There is evidence that the rate at which the pustule develops is an index of immunity resulting from the previous vaccination (McKinnon and Defries 1931).

For human vaccination, calf lymph is generally employed, but it has been shown that lymph taken from vaccinial lesions in other animals, such as the sheep or the water buffalo, can be used satisfactorily. Of late years two other types of vaccine have been introduced, partly to provide a bacteria-free product, partly to avoid the severe local and constitutional reactions to which calf lymph sometimes gives rise, and partly in the hope of preparing a vaccine of constant virulence. The first is the so-called Rivers vaccine, prepared by growth of the virus in a chick embryo tissue culture medium (see Rivers 1931, Rivers and Ward 1935); the second is the vaccine produced by Goodpasture and Buddingh (1933, 1935), who cultivate the virus on the chorio-allantoic membrane of the developing chick embryo. Neither of these vaccines has yet been tried on a sufficient scale to justify a critical assessment of their value. The available evidence suggests that neither is quite as good as calf lymph in the degree of protection to which it gives rise, but further observations are desirable (see Buddingh 1937, 1943, Lehmann 1938, Stevenson and Butler 1939, Rivers, Ward and Baird 1939, Ellis and Boynton 1939, Donnally 1939).

Vaccination itself may be carried out by scarification, by the multiple pressure method (see Leake 1927), by intracutaneous injection (see Force 1927, Toomey and Hauver 1928, 1929), or by subcutaneous inoculation (see Yaoi 1934, 1936). None of these methods seems to be effective unless an epidermal vesicle is produced; and as the intracutaneous and the subcutaneous methods often fail to give rise to vesicle formation, their use is not to be strongly advocated (see Henderson and McClean 1939). The desire to reduce the local vaccinial lesion to a minimum has led many workers to advocate the use of vaccination by the multiple pressure method or by a single tiny scratch; but the evidence given below on the relation between the amount of foveation and the diminution in the case mortality from smallpox should suggest caution in the adoption of these methods. For primary vaccination during infancy or early childhood and for re-vaccination there is much to be said for the use of the 3- or 4-scratch method, each scratch being about $\frac{1}{4}$ inch long. The milder methods of vaccination are best reserved for late primary vaccinations and for persons in whom it would be unwise to risk a severe local or general reaction.

Protective Effect of Vaccination.—The evidence that vaccination protects against smallpox is very strong, but unfortunately exact statistical evidence is difficult to obtain. This holds particularly with regard to protection against infection as opposed to death; for, from the nature of the case, it is impossible in a diffuse population to be certain of the degree of risk to which the individual

members have been exposed. On the other hand, a large body of statistical evidence has been accumulated to show that the case mortality from smallpox is greatly diminished by vaccination. This evidence is as follows:

(1) Vaccination diminishes the case mortality. Table 183 gives the figures collected by Cameron (see Report 1928*a*) for the case mortality of smallpox in vaccinated and unvaccinated persons treated in the Metropolitan Asylums Board Hospitals during 1901–04.

TABLE 183

Year.	Vaccinated.			Unvaccinated or Doubtful.		
	Admitted.	Died.	Percentage Case Mortality.	Admitted.	Died.	Percentage Case Mortality.
1901 . . .	1,282	127	9·9	461	165	35·8
1902 . . .	5,663	578	10·2	2,253	759	33·6
1903 . . .	245	7	2·9	110	5	4·5
1904 . . .	289	14	4·8	160	13	8·1
Totals . .	7,479	726	9·7	2,984	942	31·57

It will be seen that the mortality amongst the unvaccinated was more than three times that amongst the vaccinated. Macdonell (1901–02) found that in the outbreaks in Sheffield, Dewsbury, Leicester, and Warrington in the 1891–93 epidemic, the correlation between vaccination and mildness of disease was + 0·7935, and in Glasgow as high as + 0·9123.

(2) The greater the amount of foveation, the greater is the diminution of the case mortality (see Table 184).

TABLE 184

	Admitted.	Died.	Percentage Mortality.
With 4 scars or more . . .	3,139	171	5·4
„ 3 „	1,902	171	9·0
„ 2 „	1,442	184	12·8
„ 1 scar	930	168	17·9

(3) The greater the area of cicatrix left by the vaccination, the greater is the diminution of the case mortality (see Table 185).

TABLE 185

Area of Scar.	Admitted.	Died.	Percentage Mortality.
Area of $\frac{1}{2}$ sq. in. or more . .	5,564	388	7·0
„ $> \frac{1}{3}$ sq. in. but $< \frac{1}{2}$ sq. in.	889	138	15·5
„ $< \frac{1}{3}$ sq. in.	933	158	16·9

According to Turner (1905–06), among cases with equal total areas of vaccination scarring there is no difference in the amount of protection afforded by different numbers of scars.

(4) In vaccinated persons the mortality from smallpox increases with the length of time elapsing since vaccination. Table 186 affords a comparison, in this respect, between vaccinated and unvaccinated persons. This table also shows a very different age-grouping of admissions in vaccinated and unvaccinated persons, strongly suggesting that vaccination affords protection against infection as well as against death.

TABLE 186

Years.	Vaccinated.			Unvaccinated and Doubtful.		
	Admitted.	Died.	Percentage C.M.	Admitted.	Died.	Percentage C.M.
–10 . .	143	2	1·4	1,441	459	31·9
11–20 . .	1,218	23	1·9	761	166	21·8
21–30 . .	2,675	144	5·3	374	129	34·5
31–40 . .	1,861	247	13·3	180	80	44·4
41–50 . .	893	174	18·2	102	57	55·9
51–60 . .	311	55	17·7	73	31	42·5

A striking piece of evidence in favour of the value of vaccination is afforded by the fact that of the 4,406 cases of smallpox in vaccinated persons in England and Wales during the period 1921–26 only 3 were under 12 years of age. This observation is difficult to explain except on the hypothesis that vaccination during infancy confers a large measure of protection against the disease lasting for some years. Vaccination performed immediately prior to exposure to smallpox (the incubation period of which is 12 to 14 days) affords almost absolute protection against the disease. Vaccination performed during the incubation period of smallpox either prevents the development of the disease, or predisposes to a modified form of the disease. Similarly, recent successful revaccination is said to afford an almost absolute protection against smallpox (Brownlee 1905–06).

In the United States there is a very interesting relationship between the vaccination laws in the different states and the incidence of smallpox (Table 187).

TABLE 187

RELATION OF SMALLPOX MORBIDITY TO VACCINATION LAWS IN THE UNITED STATES, 1919–28. (Woodward and Feemster 1933.)

Vaccination Laws.	No. of States.	Population.	No. of Cases.	Incidence per 100,000.
Compulsory vaccination	10	32,434,954	21,543	6·6
Local option	6	17,930,882	91,981	51·3
No vaccination laws	29	59,923,117	393,924	66·7
Compulsory vaccination prohibited .	4	4,002,888	46,110	115·2

The effect of vaccination appears to wear off with increasing age, as can be judged from Table 186; and it is therefore advisable, in countries where smallpox is rife, to perform revaccination every three years. In other countries vaccination

every five or ten years should suffice, provided revaccination is performed if the disease is introduced into the locality. Primary vaccination is, as a rule, best carried out during the first year of life. It should be deferred for at least 3 months after birth to enable the passive immunity received from the mother to wear off (Béclère 1936). (For general discussion of vaccination, see Greenwood 1930, 1935, Report 1931, Russell 1941, Robinson 1941.)

Complications of Vaccination.—Of the complications that may follow vaccination, suppuration is one of the commonest, and tetanus one of the most serious. Owing to the use of calf lymph, which cannot be satisfactorily sterilized, the introduction of micro-organisms into the wound is inevitable, but it is very difficult to say how often the calf lymph is responsible, and how often uncleanliness on the part of the operator, or during the after-treatment. Occasionally, as at Malmö, severe necrotic lesions may occur owing to the presence of pathogenic staphylococci in the lymph (Magnusson 1932, 1933). It may be noted that foot-and-mouth virus has been found occasionally in specimens of calf lymph, though there is no evidence that its presence had excited any unfavourable reaction in vaccinated children (see Gildemeister 1931, Gildemeister and Helm 1932*a*, *b*).

Tetanus is a very rare complication; thus in 1904–13 in the United States, 31 million lymph doses were inoculated into human beings, and only 41 cases of tetanus were observed. Infection in these cases may be carried by the lymph; but tetanus occurs only in those cases in which a protective shield or dressing strapped to the arm has been applied. Vaccination insertions treated openly have never been followed by tetanus (Armstrong 1927).

Generalized vaccinia is a serious complication, which is estimated to occur in 1 out of every 30,000 subjects vaccinated. Persons with chronic skin lesions are said to be specially susceptible. The disease varies from a mild rash with a few scattered vesicles and little constitutional disturbance to a severe variola-like disease with tracheitis, general glandular enlargement, widespread affection of the skin, and a rapid course to death. The case mortality is said to be 30–40 per cent. (see Ross 1941).

In recent years, a new complication has been observed, namely, *post-vaccinal encephalitis*. The first case studied in detail was observed by Turnbull in 1912; but it was not till the publication of Turnbull and McIntosh's report in 1926 that serious attention was drawn to the subject. Altogether in this country and abroad, some hundreds of cases have been observed, though the disease is now very much less frequent than formerly (Report 1936). Most of them have occurred after late primary vaccination. Vaccination during the 1st year of life rarely seems to be followed by encephalitis. Clinically, after an incubation period of 10 to 14 days, there is a rapid onset followed by an acute course, the symptoms being cerebral rather than spinal (Report 1928*a*). The morbidity is given by Ross (1941) as 1 in 100,000 cases, but it may be as high as 1 in 8,000 (see Fyfe and Fleming 1943); probably 1 in 50,000 is an average figure. The mortality, among 62 cases recorded by the Committee on Vaccination, was 58 per cent. Histologically, the lesions are widely distributed in the grey and white matter of the brain and cord, and are characterized particularly by extra-vascular parenchymatous infiltration with large endothelial and glial cells, and by perivascular areas of softening or demyelination (McIntosh 1928). The ætiology of these cases is as yet unknown. Greenfield (1928) suggests that, as the lesions are similar in many respects to those seen in encephalomyelitis following measles and in

disseminated sclerosis, the encephalitis is caused by some neurotropic virus which is capable of causing a latent infection, and may be stimulated into activity either by vaccination or by some exanthematous infection. This is the view favoured by the Committee on Vaccination (Report 1928*a*, 1930). McIntosh (1928), on the other hand, believes that post-vaccinal encephalitis is due to the vaccinia virus itself, because: (1) a similar encephalitis may occur in cases of smallpox; (2) the vaccinia virus has been recovered from the brain of cases of post-vaccinal encephalitis; (3) by the intracerebral injection of a neurotropic strain of the vaccinia virus, it is possible to produce in rabbits an encephalitis which he regards as essentially similar to that observed in human beings after vaccination. Each of these views has a substantial following (see Berger 1929, McIntosh 1930, McIntosh and Scarff 1930, Hurst and Fairbrother 1930, Clearkin 1930, Herzberg-Kremmer and Herzberg 1930, Eckstein 1931, Lucksch 1932, Armstrong 1932, Rivers *et al.* 1933, Ledingham 1934, Aldershoff 1935). (See also secondary encephalitis, p. 1921.)

The production of potent *antivaccinial sera* has now been shown to be possible (Ledingham *et al.* 1931, Fairbrother 1932), and there may be some call in the future for such sera, or for sera prepared against the variola virus, in the treatment of smallpox. Human convalescent blood or serum has been advocated by some workers, but this method of treatment is still in the experimental stage (see Yaoi 1935, Couzi and Kircher 1943). *Sulphonamides* are apparently without action on the virus itself, but they may be of value in the treatment of septic complications (Wilkinson 1942).

The Animal Poxes, including Avian Diphtheria or Roup

Pox occurs in a number of animals, such as sheep, goats, cows, horses, swine, fowls, and pigeons. The clinical manifestations vary; in its typical form it occurs as a vesico-pustular eruption on the skin, sometimes associated with very marked epithelial proliferation; on the other hand it may, as in horses, produce an eruption in the mouth (contagious pustular stomatitis), as well as on the skin; or, as in fowls, diphtheritic pseudo-membranes in the throat (avian diphtheria or roup). Histologically, inclusion bodies of the Guarnieri type are found in the lesions.

Whether the virus responsible for the animal poxes is identical with that responsible for vaccinia in man, or whether each virus is specific for its particular host is not yet clear, but evidence is rapidly accumulating to suggest that it is the vaccinia virus itself or some variety of it. Thus it is usually possible, by rabbit passage, to convert the mammalian pox viruses into a virus indistinguishable in its action on rabbits and human beings from the vaccinia virus (Toyoda 1924). Moreover animals inoculated with one variety of virus are more or less completely protected against another variety (see also Borrel 1903, Bosc 1903, de Jong 1917, Zwick 1924, von Wasielewski and Winkler 1925, Ledingham 1926).

Sheep-pox, known in France as *la clavelée*, is of some economic importance. It was studied by Borrel in 1903 who noted the occurrence of distinctive cellular bodies in the lesions, and showed that the causative agent was able to pass through coarse Chamberland filters. The virus has been cultured by Gins and Kunert (1937) on the chorio-allantoic membrane of the chick embryo.

The disease, which runs an acute febrile course, is characterized by the development of a vesicular eruption, later becoming pustular, on the more exposed parts

of the body. Infection can readily be transmitted to normal sheep by inoculation with the serous fluid contained in the loculated vesicles. The case mortality of the natural disease is very low. Post-mortem examination of fatal cases reveals the presence of generalized lesions. The lungs contain multiple, small, dense, spherical nodules, hyaline in appearance with a central opaque spot; they are commonest near the pleural surface. Similar, but less obvious, lesions are also seen in the liver and kidneys. Prophylactic inoculation with a sensitized vaccine is widely practised in France (Bridré and Boquet 1923, 1933). Inoculation with vaccinia virus is said to protect sheep against sheep-pox (Gins and Kunert 1937).

Rabbit-pox has recently been submitted to a careful experimental study by Pearce and her colleagues (Pearce *et al.* 1936*a*, *b*, Rosahn *et al.* 1936*a*, *b*, Hu *et al.* 1936). The virus is filtrable through Berkefeld V candles; it is antigenically related to the vaccinia virus, but not to Virus III (see p. 1909), or the virus of infectious myxoma (see p. 1978); and it is able to infect guinea-pigs, mice, calves, and probably rats.

Fowl-pox requires separate consideration. According to Doyle (1929) three clinical forms may be recognized: (1) wart-like nodules on the comb, wattles, and skin of the head; (2) adherent, yellow, cheesy membranes in the mouth; (3) a watery or muco-purulent discharge from the eyes and nose; this form is sometimes referred to as "roup." One, or any combination, of these forms, may be present in the same bird. These clinical forms have long been regarded as separate diseases, but the evidence now accumulating suggests that they are caused by one and the same filtrable virus, though the possibility that similar clinical conditions may be due to other agents cannot be excluded. Moreover, recent work suggests that the fowl-pox virus is related to the vaccinia virus. Thus Toyoda (1924) maintains that by passage through rabbits the fowl-pox virus can be converted into the vaccinia virus. Findlay (1928), however, has been unable to confirm this. The exact relationship between these two viruses must be left for the future to determine, but in any case the fowl-pox virus, both in its pathogenicity and in its serological reactions, seems to be less nearly related to the vaccinia virus than are the mammalian pox viruses. In the lesions of fowl-pox so-called Bollinger inclusion bodies, and Borrel elementary bodies, corresponding respectively to the Guarnieri corpuscles and the Paschen bodies in vaccinia, can be found (see Ludford and Findlay 1926).

Doyle and Minett (1927) found that pigeons were resistant to fowl-pox virus, but that fowls were susceptible to the virus of pigeon-pox. Moreover, they obtained evidence that pigeon-pox protected fowls against fowl-pox. Following on these observations, Doyle (1930) introduced the prophylactic vaccination of fowls with a vaccine consisting of dried pigeon-pox crusts suspended in glycerolated saline. This method is now being used on a wide scale with apparently very favourable results. The relationship of the two viruses is not very clear, but according to Doyle (1930) repeated passage of the pigeon-pox virus through fowls leads to an increase in its virulence for the latter; after 9 passages it may acquire all the characteristics of the typical fowl-pox virus.

Kikuth and Gollub (1932) have described a disease of canaries, which appears to be **canary-pox.** It has been studied by Burnet (1933) and Burnet and Lush (1936*a*), who find that the clinico-pathological picture differs from that of fowl-pox, but that the viruses of the two diseases are antigenically closely related.

One very interesting property of the pox viruses is their power to give rise in

certain hosts—sheep and fowls particularly—to tumours characterized by epitheliomatous proliferation, superficially resembling neoplasms. For a discussion on the relation of the animal pox viruses to vaccinia virus and to each other, the reader is referred to a review by Findlay (1936).

Contagious Pustular Dermatitis of Sheep

Contagious pustular dermatitis is a not infrequent malady amongst sheep in this country, and has been described by several workers on the Continent. (For refs. see Glover 1928.) It is probable that natural cases occur also amongst goats. The disease varies in severity: in the mild form there are pustular lesions on the lips and surrounding tissues; in the severe form lesions occur on the oral mucosa, the vulva, the cornea, and on various other parts of the body, particularly the regions of the coronet and the tail. Sheep of any age may be attacked, but the disease is commonest in weaned lambs up to 1 year old. Experimentally vesico-pustular lesions can be produced by scarification of the thighs of normal lambs, or by intradermal inoculation of the lip with a suspension of dried crusts from the natural lesions; the crusts generally prove active in a dilution of 1/50,000. All attempts to transmit the disease to laboratory animals have failed. Glover (1928) has brought evidence to suggest that the ætiological agent is a filtrable virus; he was able to show that Berkefeld V filtrates of scrapings of these fresh lesions, autolysed at 37° C. for 3 hours before filtration, or of the dried crusts submitted to tryptic digestion, were infective for normal lambs. The virus in the dried crusts resists desiccation for at least 4 months. Under natural conditions the disease appears to be highly infectious. Animals that have recovered from the disease possess a high degree of immunity, sufficient to protect them against re-infection for at least 8 months.

HERPES

Herpes simplex.—Herpes simplex or febrilis occurs in two forms. In the first form—often known as *herpes labialis* small vesicles, which are almost always bilateral, occur on the muco-cutaneous borders of the mouth or nostrils of patients suffering from a variety of diseases, of which pneumonia is the commonest. In the second form, the lesions occur in the mouth itself, constituting the disease referred to variously as *aphthous stomatitis*, ulcerative stomatitis, and acute infectious gingivo-stomatitis (see Black 1938). It affects mainly children and, like labial herpes, may recur from time to time. The observations of Dodd, Johnston and Buddingh (1938) showed that this second form, the ætiology of which had remained persistently obscure, was in all probability a primary herpetic infection. The further observations of Burnet and Lush (1939*b*) and of Scott and Steigman (1941) leave little doubt of the essential correctness of this conclusion. The disease should therefore be called *herpetic stomatitis*. Both forms of the disease tend to be recurrent.

Inoculation of the vesicular fluid on to the scarified cornea of a rabbit leads to the development of a severe keratitis, which can be propagated indefinitely by passage. If fluid is taken from an early keratitis in the rabbit, it is possible to produce with it specific lesions in a number of different tissues, such as the

skin, buccal mucosa, trachea, liver, adrenal, ovary, salivary glands, brain, and spinal cord (Goodpasture and Teague 1923–24*a*, Urbain and Schaefer 1927, Smith 1931*a*). Intracutaneous inoculation of human vesicular fluid produces in the rabbit an insignificant papular eruption, but once it has become adapted to the rabbit's tissues, the virus gives rise to a local herpetic lesion ; this method is of considerable value in the titration of infective material. Direct inoculation of human vesicular fluid on to the pad of the guinea-pig's foot is uniformly followed by the development of local vesicular lesions (Bedson 1934). A certain proportion of rabbits inoculated on the cornea develop, after a few days, a fatal encephalitis, characterized by widespread small-celled infiltrations, intense nerve-cell degeneration, and diffuse proliferative changes of some of the fixed elements of the tissue affected (da Fano 1923). Direct intracerebral or subdural inoculation of vesicular fluid into rabbits gives rise to a meningo-encephalitis which proves fatal in about 5 days, and which is transmissible in series to other rabbits by inoculation of the brain suspension.

Rabbit brain is highly infective, but its infectivity can be increased by homogenization —a process which probably acts by disintegration of the cells and liberation of the virus particles in a free form. Freshly homogenized virus may prove fatal on intracerebral inoculation into rabbits in 12–30 hours, and even one ten-millionth of a gram of infected brain tissue may kill the animals within 5 days (Buggs and Green 1936).

Experiments with monkeys have not given uniform results, but according to Teissier, Gastinel and Reilly (1925) cutaneous inoculation in *Callithrix* may result in the development of vesico-pustules, though often merely small papules appear. Corneal or intracerebral inoculations were without effect.

The virus can be passed from rabbits to mice by intracerebral inoculation with the brain of a rabbit suffering from herpes encephalitis, or with the ground-up nictitating membrane of a rabbit in which the corneal reaction is well established (Steigman and Scott 1942). Encephalitis develops in 3–10 days. Infection can be maintained indefinitely by passage through mice (Andervont 1929). With a neurotropic strain, cutaneous inoculation or intranasal infection of mice gives rise to encephalitis (Gildemeister and Ahlfeld 1936, Berry and Slavin 1943, Slavin and Berry 1943).

The herpes virus can be grown easily in tissue cultures, one of the most suitable media being rabbit testis (Parker and Nye 1925*b*, Gildemeister *et al.* 1929, Smith 1931*b*). It can also be adapted to grow on the chorio-allantoic membrane of the developing chick embryo. Since pocks are formed on the membrane, this method lends itself to the titration of virus and of neutralizing antiserum (Burnet 1936, Burnet and Lush 1939*a*, Shaffer and Enders 1939). In the vesicular fluid the virus is present in the form of elementary bodies, which can be stained by suitable means (Taniguchi *et al.* 1934). Examination of the corneal lesions in rabbits during the first 24 hours reveals the presence of large numbers of acidophilic intranuclear inclusion bodies—referred to as " α-bodies " by Lipschütz (1921) (Fig. 301). The diameter of the virus particles themselves is about 125 mμ. Though the virus may be demonstrated in the blood after intratesticular, and occasionally after intracutaneous, inoculation of rabbits (Gildemeister and Heuer 1929), the work of Goodpasture and Teague (1923–24*b*) seems to show that it may enter the peripheral nerves—sensory, motor, or sympathetic—from a local lesion and reach the central nervous system, where it is liable to give rise to a myelitis or encephalitis (see also Burnet and Lush 1939*c*, Berry and Slavin 1943).

Rabbits that have passed through an attack of experimental keratitis possess a considerable degree of immunity to subsequent corneal, or even intracerebral, inoculation (Levaditi and Nicolau 1922). This immunity appears to depend largely on the development of humoral antibodies (Bedson and Crawford 1927, Schultz and Hoyt 1928). Bedson and Bland (1929) were able to obtain specific complement fixation with the herpes virus in the presence of serum from the hyper-immunized guinea-pig. Antibodies may also be demonstrated in a considerable proportion of children and adults, either by a specific neutralization test (Zinsser and Tang 1929, Andrewes and Carmichael 1930), or by complement fixation (Brain 1932). Burnet and Lush (1939*b*) and Burnet and Williams (1939), working in Melbourne, found neutralizing antibodies present in over 90 per cent. of children and adults of the hospital classes, but in only about 50 per cent. of members of the higher social classes. This they explain by the greater frequency of primary herpetic stomatitis in early life among children of the lower classes. Since recurrent herpes affects persons whose blood serum contains neutralizing antibodies, it is assumed that the virus persists in the body tissues—probably in the mouth (Scott and Steigmann 1941)—and that immunity is to a considerable extent non-specific. The failure of the antibody to afford protection is curious. Herpes febrilis constitutes, in fact, one of the most striking exceptions to the general rule that filtrable virus infections usually leave behind them a solid and lasting immunity. A skin reaction that is said to be positive in persons subject to recurrent attacks of herpes has been described by Nagler (1944).

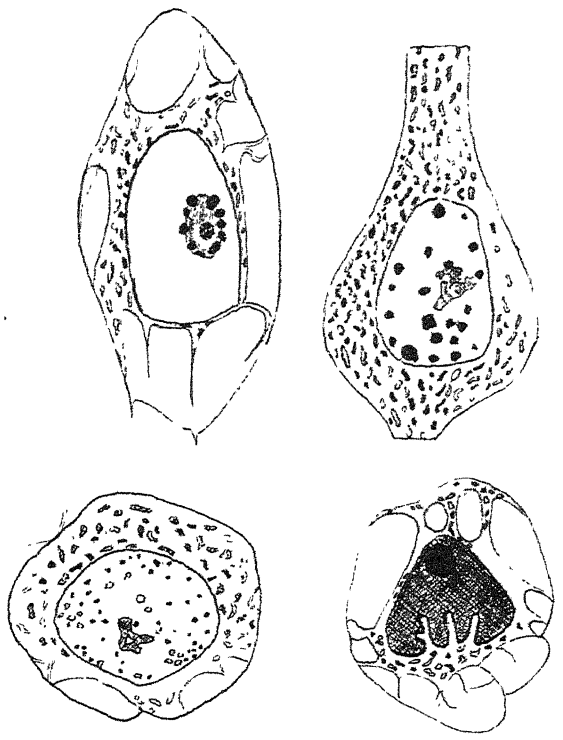

FIG. 301.
Intranuclear inclusion bodies in nerve cells of rabbits experimentally infected with herpes febrilis.
(After Cowdry and Nicholson 1924.)

Keratitis herpetica of human beings was shown by Grüter in 1912–14 to be transmissible to rabbits by inoculation of the scarified cornea. This observation was confirmed by Luger and Lauda (1921), who found, histologically, alterations in cellular structure similar to those in herpes febrilis. These consisted of giant-cell formation, the characteristic ballooning degeneration of Unna, and bodies which they considered to be due to a specific degenerative reaction of the nucleus, but which Lipschütz regards as inclusion bodies.

Herpes genitalis has likewise been shown to be transmissible to rabbits, but the keratitis set up by the genitalis virus is much less severe than that set up by the febrilis virus. Similarly, on subdural inoculation the genitalis virus is less virulent; by this route the febrilis virus uniformly produces encephalitis in rabbits, fatal in 4 to 6 days; the genitalis virus does not uniformly produce encephalitis, and, when it does, the rabbits do not die for 5 to 17 days (Blanc and Caminopetros 1924). Lipschütz (1921) succeeded in transferring genital herpes to human beings. Both in the human lesions and in the rabbit's cornea, he found nuclear inclusion bodies of the so-called β-type present in large numbers; they are best looked for in the rabbit's cornea on the 3rd day after inoculation. He was unable to produce immunity to the genitalis virus by inoculation of the rabbit's cornea with the febrilis virus. He therefore regards the two viruses as distinct.

Herpes zoster.

Herpes zoster differs clinically from herpes febrilis in forming large vesicles or bullæ, in occurring on the trunk, in being almost always unilateral, in being accompanied by sharp neuralgic pains, in being distributed along the course of sensory nerves, and in being non-recurrent. Experiments made to ascertain whether zoster is transmissible to animals have given most conflicting results.

Lipschütz (1921) claimed to have produced keratitis in rabbits with material from 3 out of 7 cases of zoster. Both in human lesions and in the rabbit's cornea, he found acidophilic nuclear inclusion bodies, which he calls "zoster bodies." In the rabbit's cornea these bodies were present in greatest numbers on the 4th day after inoculation. The keratitis, when it did develop, was mild, and consisted of small round vesicles, which did not appear till the 4th day, and which after a few days tended to regress. Kundratitz (1924–25) claimed to have transmitted zoster to infants; in contradistinction to herpes febrilis, in which the incubation period of the experimental human disease is only 24 to 48 hours, the incubation period in zoster was 12 to 15 days. Teague and Goodpasture (1923–24) obtained some evidence that the zoster virus differed from that of herpes febrilis mainly in its degree of virulence, but their experiments were not very satisfactory.

Cole and Kuttner (1925) failed to confirm the work of either Lipschütz, or Teague and Goodpasture. Using material from 9 cases of zoster, they performed corneal and intracerebral inoculations on rabbits; they inoculated *rhesus* monkeys by the cerebral, cutaneous, neural, and corneal routes, and vervet monkeys by the testicular route; and they rubbed the material on to the scarified tar-painted skin of rabbits and guinea-pigs —all with negative results. Since herpes febrilis can be easily transmitted to rabbits, while zoster either cannot be transmitted at all or only irregularly, they conclude that the two diseases are ætiologically distinct. Seidenberg (1931) was likewise unable to produce keratitis or orchitis in the rabbit with vesicular fluid from zoster patients; and the cornea of rabbits inoculated with zoster virus was found to be still susceptible to the virus of herpes febrilis.

More recently Goodpasture and Anderson (1944) have succeeded in growing the zoster virus on pieces of human skin grafted on to the chorio-allantois of the developing chick embryo. Microscopic lesions becoming pustular were produced on the skin under these conditions, though not true vesicles; and intranuclear acidophilic inclusion bodies were demonstrable in the affected epithelial cells. The chicken-pox virus, it may be noted, could not be cultured in this way.

Elementary bodies may be demonstrated by suitable staining methods in zoster vesicles, particularly during the first 48 hours (Amies 1934, Taniguchi *et al.* 1934). It seems probable that they constitute the specific virus of the disease.

Summarizing, it would appear that the viruses of herpes febrilis, genitalis, and zoster all differ from each other; the febrilis virus is the most virulent for the rabbit and the zoster virus the least. Whether they are to be regarded as distinct species of virus, or as varieties of the same species, it is at present impossible to say.

For the relation of herpes zoster to varicella see below.

VARICELLA

Chicken-pox appears to be due to a virus, which can be demonstrated by suitable staining methods in the vesicular fluid (Aragão 1911, Paschen 1919, Taniguchi *et al.* 1932*b*). The virus particles, or elementary bodies, are of coccoid form, and are arranged singly, in pairs, or in short chains. The virus is of very low infectivity for animals. The disease is characterized histologically by the presence of intranuclear acidophilic inclusion bodies in the epithelial cells (Tyzzer 1906), indistinguishable from those described by Lipschütz (1921) in zoster. Rivers and Tillett (1923, 1924*a*, *b*) and Taniguchi and his colleagues (1932*b*) reported transmission of the virus to the rabbit's testicle, but subsequent observations leave little doubt that they were working, not with varicella virus, but with the so-called Virus III (see p. 1909). On the other hand, the presence of acidophilic intranuclear inclusion bodies in the testicles of vervet monkeys inoculated with material from human chicken-pox lesions were probably the result of infection with the true varicella virus (Rivers 1926, 1927).

Amies (1933) has described a specific agglutination reaction, using as antigen a 0·25 per cent. formolized suspension of elementary bodies prepared by the differential centrifugation of human vesicular fluid. Of 55 sera taken from patients 2–12 days after the onset of the attack, 35 contained agglutinins in a titre of 1/4–1/256, while 20 gave negative results. Antibodies appear about 5 days after the onset, and persist for some considerable time. Convalescent serum has apparently no prophylactic value (Lewis *et al.* 1937).

Relation between Herpes zoster and Varicella.

A large body of clinical evidence has been produced suggesting that zoster and varicella are closely allied diseases. The experimental evidence in favour of this conception has been summarized by Lipschütz and Kundratitz (1925) as follows: (1) In infants inoculated with zoster material, apart from the local vesicles that develop, a general varicella-like eruption may occur; (2) children brought into contact with infants inoculated with zoster may develop chicken-pox; (3) inoculation experiments with zoster, made on children who have recovered from varicella, prove negative; (4) inoculation experiments with varicella, in children who have recovered from natural or experimental zoster, prove negative; (5) the serum from patients convalescing from zoster has a protective action against varicella; (6) both varicella and experimental zoster have the same incubation period; (7) similar cytological appearances are found in both diseases.

On the other hand, there are a number of differences (Barrett 1938). For example, zoster is not contagious: chicken-pox is highly contagious. A leucopenia with a relative mononucleosis is the rule in chicken-pox, but not in zoster. Chicken-pox affords almost complete immunity against chicken-pox, but not against zoster. Zoster affords almost complete immunity against zoster, but not against chicken-pox. Chicken-pox is much commoner in zoster contacts than zoster is in chicken-pox contacts.

The close relationship of the two diseases to each other is supported by the observations of Netter and Urbain (1924, 1926, 1931), who found apparently identical antibodies, demonstrable by the complement-fixation test, in the serum of patients with zoster and varicella. Brain (1933), moreover, obtained equally good fixation with zoster and with varicella vesicular fluids. It has further been shown that serum from convalescent zoster patients often agglutinates a suspension of varicella elementary bodies, though to a rather lower titre than a suspension of zoster elementary bodies. On the other hand, Hasskó, Vámos and Thoroczkay (1938) never obtained complete cross-fixation of complement between varicella and zoster sera; and in a high proportion of sera no cross-fixation occurred at all. As already noted, Goodpasture and Anderson (1944) were able to cultivate the zoster virus on pieces of human skin that had been grafted on to the chorio-allantois of the developing chick embryo, but failed to grow the chicken-pox virus under these conditions. The evidence, on the whole, suggests that the two diseases are caused by viruses that are closely related to each other, but are probably not identical.

Epidemic Keratoconjunctivitis

The inclusion of epidemic keratoconjunctivitis among the filtrable virus group must, for the present, be tentative. According to Smitmans (1940), this disease was recognized in Vienna as long ago as 1889. It has been known in India for several years, but it assumed special prominence during the second world war, when it was reported from Germany (Smitmans 1940) and from the United States (Sanders 1942, Rieke 1942). It was very common in shipbuilding yards. It is characterized by redness, swelling and sometimes vesiculation of the conjunctiva. There is a relative absence of conjunctival discharge; what there is, is sero-mucoid, seldom purulent. The disease is mainly unilateral, but the second eye often becomes affected. In about half the cases inflammation extends to the cornea, but corneal scars are said to be left in only 1 to 10 per cent. of the patients. Nasal catarrh is sometimes present at the onset, headache and malaise are common systemic manifestations, and enlargement of the homolateral pre-auricular gland is almost invariable. The disease lasts, as a rule, about 2 to 4 weeks, and is irresponsive to treatment. No pathogenic bacteria have been isolated, but the observations of Sanders (1942), Sanders and Alexander (1943), and Sanders, Gulliver, Forchheimer and Alexander (1943) suggest that the disease is of virus origin. These workers record the isolation of a virus from two patients. At first it could be maintained only in tissue culture, but later it was adapted to the mouse brain. Intracerebral inoculation of mice gave rise in 2 to 7 days to a disease characterized by lethargy, tonic and clonic convulsions, sometimes spastic paralysis, and death within 24 hours of the onset of symptoms. The virus passed through collodion membranes of 75 but not of 50 mμ, suggesting that it was probably about 25 mμ in diameter. It was neutralized by serum from convalescent patients. Inoculated into the eye of a human volunteer, the mouse virus produced a mild but characteristic attack of keratoconjunctivitis, followed by the appearance of neutralizing antibodies in the patient's serum. The disease does not appear to be highly contagious from patient to patient, but it is readily transferred by indirect means. Rigid precautions are necessary to prevent infection from one patient to another by instruments and hands in the surgery. Patients should be isolated, and contacts kept under observation. Intravenous inoculation of human convalescent serum is said to be of benefit (Braley and Sanders 1943).

FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease is a highly infectious disease of cloven-footed animals. Cattle, pigs, sheep, and goats are chiefly affected; reindeer and camels are susceptible. Occasionally human beings contract the disease (see Flaum 1939). Epidemics occur from time to time in most countries, the disease remaining endemic in the intervening periods. In this country the disease is not strictly endemic, but outbreaks occur from time to time, occasionally reaching epidemic proportions. In the year 1923, for example, 1854 separate outbreaks were reported, necessitating the slaughter of 125,098 animals.

The disease is usually mild, causing a mortality in cattle of not more than 2–3 per cent., and a slightly higher mortality in sheep and pigs; on the Continent, however, a malignant form sometimes occurs, causing in young animals a mortality of 50–70 per cent. The importance of the disease lies not so much in the deaths to which it gives rise as in the debilitating effect it has on the general health of the animals, leading to a fall in milk and meat production. The incubation period is 2 to 7 days. Infection usually occurs from animal to animal, the infective material coming into contact with the mucosa of the mouth, nose or conjunctiva, or with an abraded skin surface. Cases of direct infection are easy to understand; the real problem lies in explaining the origin of foot-and-mouth disease in animals that have not, so far as can be ascertained, been in contact with infected animals. Numerous explanations have been offered of these cryptogenic cases. Thus it is supposed by some that infection is carried by contaminated hay, straw, milk, drinking water, clothes, and other objects. In support of this, it has been found that the virus may survive on chopped hay at room temperature for at least 15 weeks, and on bran for at least 20 weeks (Report 1927). Moreover, there is evidence that the virus may resist putrefaction for long periods (Report 1928*b*). In this way it is possible to understand how infection may lie dormant for months in dried discharges or in carcasses of infected animals. That the virus may not only remain alive, but may keep its virulence under these conditions, was shown by the development of foot-and-mouth disease in a calf fed with hay that had been contaminated 1 month previously with infected saliva, and in pigs fed on crushed bones from the frozen carcasses of infected animals that had been killed several weeks previously (Report 1927).

Another explanation is that the virus is carried by human and animal agencies. Thus it has been suggested: (1) That birds, particularly starlings, may carry infectious material on their feet; for this there is no direct evidence (see Bullough 1942). (2) That wild rodents may carry the disease and transmit it to cattle, sheep, and pigs coming into contact with them (see Beattie *et al.* 1928). Many of these rodents are susceptible to experimental infection, but practically all experiments designed to test the possibility of natural spread amongst them have given negative results. The virus has, however, been demonstrated in hedgehogs on an infected farm. Experimentally, it has been found that healthy hedgehogs placed in contact with affected cattle may themselves become infected, and that a healthy cow placed in a stall with infected hedgehogs may develop typical foot-and-mouth disease (Report 1937). (3) That the virus may gain access to, and persist on, the nasopharyngeal mucosa of human beings, who can then act as healthy carriers of the disease; for this there is a certain amount of

epidemiological, but no direct experimental evidence (Kling and Höjer 1926). (4) That infected cattle may remain as chronic carriers; it has been found that infective material may persist on the hoofs for some time after recovery from the disease, but this appears to be an exceptional occurrence (Gins and Krause 1923). Animals that have recovered from the disease may excrete the virus in the urine, but how often urinary carriers occur is still in doubt (Waldmann *et al.* 1931). The experimental evidence so far collected does not favour the view that chronic carriers are common. On the other hand, there is a considerable amount of epidemiological evidence to suggest that infection is introduced into a herd by means of apparently healthy animals coming from another herd. Moreover, if the virus could persist on the healthy mucosa of animals, or remain latent in their tissues, it would not be difficult to understand how outbreaks of the disease might occur in herds that had had no demonstrable contact with the disease. At the present time it is impossible to come to any definite conclusion on the most common method of indirect infection; but the Foot-and-mouth Disease Research Committee (Report 1928*b*) favour the view that the persistence of the virus in dried discharges on fodder, hair, and other materials, and in carcasses, is of greater epidemiological significance than its carriage in the body of recovered animals.

Experimental Reproduction of the Disease.—The disease can be experimentally reproduced in cattle, sheep, and pigs by rubbing infective material from the foot-and-mouth lesions into the scarified mucosa of the lip or mouth. Intramuscular inoculation requires a larger dose, and the effect is less regular.

In *cattle* inoculated intramuscularly, the temperature rises in 1 to 3 days to about 104° F., and the characteristic lesions appear in 1 to 5 days. Of 71 cattle that reacted to inoculation, foot and mouth lesions occurred together in 63; in the remaining 8, mouth lesions were absent (Report 1927). Great differences in the severity of the disease occur as the result of inoculating different strains of virus. Sheep inoculated intramuscularly generally show a rise of temperature to 104° or 105° F. in 18 to 48 hours. Foot lesions are constant, appearing in 1 to 3 days or so, depending on the virulence of the strain. Mouth lesions are uncommon. Pigs inoculated intramuscularly show a rise of temperature in 20 to 48 hours; foot lesions constantly develop, generally in 1 to 3 days; mouth lesions are not quite so constant, and do not appear till after 3 days.

Waldmann and Pape (1920) showed that the disease could be reproduced experimentally in *guinea-pigs* by cutaneous or subcutaneous inoculation into the balls of the fore and hind feet, or into the hairless side of the metatarsus. Not all strains, however, seem to be capable of infecting these animals.

After intracutaneous inoculation of the foot pad, there is an incubation period lasting from 12 hours to 4 days. The first signs of reaction are a rise of body temperature, and redness and swelling of the foot, followed by the development of small vesicles radiating from the line of inoculation. The vesicles coalesce to form a large tense blister over the entire sole, containing as much as 0·1 ml. of semi-transparent fluid, which is rich in virus. General symptoms of illness occur, and secondary vesicles develop on the uninoculated feet, and on the tongue, lips and gums. About 2 days after their appearance, the vesicles become greyish-white and flattened, and then gradually dry up; the whitish colour of the skin may remain for some time. The vesicles usually heal completely in 10 to 14 days. Though the animals are often ill, refuse food, and lose weight, only about 5 per cent. of them die. The remainder recover, and are henceforth highly resistant to fresh inoculation. The disease can be reproduced by intramuscular, intraperitoneal, and intravenous inoculation. After intravenous injection, vesicles develop on the legs in 3 to 4 days; mouth lesions are not usually observed (Waldmann and Pape 1920).

Maitland (1928) has brought evidence to suggest that mechanical pressure is to some extent responsible for the localization of the lesions on the pads of the feet after intramuscular injection of the virus. She found that if one foot was adequately protected from pressure by being wrapped in cotton-wool, no lesions developed on this foot after intramuscular injection, though typical vesicles appeared on the unprotected feet. Moreover, by exposing the feet to unusual pressure, as by keeping the animals in cages with a coarse wire-mesh floor, she was able to induce the formation of vesicles on the toes, and even on the dorsal parts of the feet—situations in which vesicles do not usually occur. The disease can readily be passed from animal to animal by inoculation with infective material. Complement-fixing bodies may be found in the blood serum of convalescent guinea-pigs (see Krag and Schmidt 1937).

Rabbits, rats and mice can all be infected, but the experimental disease is less severe and less typical than in guinea-pigs; dogs and cats sometimes prove susceptible; ducks can be infected by inoculation of the virus into the thickened pads of skin under the toes (Report 1937). The disease practically never spreads from experimentally inoculated to normal rodents. Even highly susceptible cattle placed in contact with infected guinea-pigs rarely contract the disease.

Properties of the Virus.—The virus is present in great concentration in the vesicle fluid of experimentally infected guinea-pigs; even when diluted 1/1,000,000 times it is generally infective for normal guinea-pigs. In the blood, during the febrile stage of the illness, the concentration is less, but even this is active in a 1/1,000 dilution (Report 1927). In cattle during the febrile stage of the disease, the saliva, urine, milk and vesicular fluid are infective; but in 3 to 6 days after the appearance of the lesions they lose their infectivity completely. For diagnostic purposes, it is therefore important to use fresh vesicular material, not more than 2 days old (Olitsky *et al.* 1928). The rapid disappearance of the virus from the local lesion and blood of infected animals is one of the most remarkable features of foot-and-mouth disease; within the space of 3 or 4 days as a rule the virus, from being present in large quantities, is reduced to such an extent that it is no longer demonstrable by experimental methods.

Loeffler and Frosch (1898) in 1897 were the first to show that the foot-and-mouth virus was filtrable. When present in diluted vesicle fluid, it will pass readily through Berkefeld, Chamberland and Seitz filters. The size of the virus is still in process of determination. Using the gradocol membrane technique, Galloway and Elford (1933) found the average particle diameter to be 8–12 $m\mu$. Centrifugation experiments, however, placed it at 20–25 $m\mu$ (Elford and Galloway 1937, Schlesinger and Galloway 1937). Barnard (1937), studying photomicrographs taken by ultra-violet light, found the diameter to be even larger—about 40 $m\mu$. The organisms tended to be rod-shaped, and the optical system used may have been incapable of resolving the smaller diameters completely; the breadth of the virus may therefore have been rather less than the figure quoted. Further work must be awaited before the discrepancy between these three estimates can be explained; but it may be noted that the gradocol membrane technique will necessarily afford a measurement of the smallest diameter of the virus—just as with spirochætes—and that the measurement afforded by centrifugation is determined by the density value, which itself is to some extent a matter of assumption. The suggestion that the A, B, and C varieties are not identical in size (see Modrow 1929) finds no support in the observations of Galloway and Elford (1937). The virus was successfully cultivated by Maitland and Maitland (1931) in tissue cultures containing guinea-pig embryo tissue and clotted guinea-pig plasma. Seventeen

successive subcultures were observed, and a titre as high as 1/100,000 was obtained (see also Hecke 1930, Striegler 1933, Köbe and Fertig 1936.

The virus is very resistant to certain methods of disinfection, though easily destroyed by others. Thus when vesicle fluid from the guinea-pig is dried rapidly on a glass slide at 37° C., it is often inactivated immediately; but if dried slowly at room temperature, and kept over H_2SO_4, it survives for 3 to 6 months. Filtered vesicle fluid is destroyed by moist heat at 55° C. in 15 to 40 minutes. The virus when present in dilute vesicle fluid is readily destroyed by high dilutions of chlorine, iodine, potassium permanganate, caustic soda, and sulphuric acid, but in epithelial scrapings it is much more resistant. Its apparent resistance to chemical disinfectants in the presence of organic matter is probably due to the protective effect exerted by the protein coagula formed in the substrate (Olitsky *et al.* 1928). If coagulation is prevented, or if disinfectants are used that do not coagulate protein, the virus is found to be very susceptible. In buffer solutions the virus shows two zones of stability—an optimal zone at pH 6·5–10·0, and a less favourable zone at pH 2·5–3·5 (Pyl and Klenk 1933, Galloway and Elford 1935). At a suitable pH it may survive in the ice-chest for a year.

Plurality of Various Types.—Immunological experiments have shown that there are at least three different types of foot-and-mouth virus. Vallée and Carré (1922) met with two types, Virus O from the Department of the Oise, and Virus A from Germany (*origine allemande*). Both viruses were equally pathogenic for cattle, pigs, and sheep, and gave rise to the same clinical symptoms. Animals that had recovered from infection with one strain proved immune to further infection with the same strain, but were readily infected by the other strain. Waldmann and Trautwein (1926), in an examination of 30 strains of different origin in Germany, encountered three types; 4 strains belonged to Type A, 4 to Type B, and 5 to Type C; the remaining 17 strains were variants of the main types. Strains of different types were found in the same area. Oxen and guinea-pigs were infected experimentally with the three different types in succession. According to the Foot-and-mouth Disease Research Committee (Report 1928*b*), Vallée's Type A is the same as Waldmann's Type B, and Vallée's Type O the same as Waldmann's Type A; Waldmann's Type C is a new type. The three types are said to be distinguishable by complement fixation (Ciuca 1929, Helm 1933).

Further observations, particularly by Manninger and von László (1930), Trautwein and Reppin (1932) and Daubney (1934), have cast considerable doubt on the fixity of these three types. Variant and intermediate types have been observed, and one intermediate strain was found to pass into an O type as the result of guinea-pig passage and into an A type as the result of storage in the cold. Daubney regards the bovine virus as a labile organism subject to spontaneous phase variations. This interpretation is borne out by observations in Great Britain (Report 1937). The epidemiological importance of multiple types is obvious, since it renders possible the re-infection of animals that have already passed through one attack of the disease.

Immunity and Prophylactic Treatment.

An animal that has passed through an attack of the disease acquires a varying degree of immunity to the specific type of infecting virus. In cattle, subsequent resistance to infection appears to be very strong, persisting for some years; but pigs develop a much lower degree of immunity and can often be re-infected within a year (Report 1937). The serum of immune animals contains antibodies capable of neutralizing the virus *in vitro*. Prophylactically, immunity may be produced

by the injection of animals with a weakly virulent virus, given either alone or in combination with immune serum. The practice of using living virus is open to several objections.

Vallée, Carré and Rinjard (1926) succeeded in rendering cattle immune by the use of a formolized vaccine, prepared by exposing the virus to a concentration of 0·5 per cent. formol for 4 to 7 days at room temperature. Heifers inoculated subcutaneously with 10 ml. of Virus A and 10 ml. of Virus O vaccine were protected against subsequent infection with either strain, though one animal proved susceptible to Virus O. Immunity can likewise be produced in guinea-pigs by use of a formolized vaccine, but the immunity is only partial, and wears off in about 2 months; moreover, antibodies are not demonstrable in the blood serum. Guinea-pigs may, however, be rendered highly resistant by the intramuscular injection of living virus, after preliminary immunization with formolized virus; and in animals so treated antibodies may readily be demonstrated in the blood (Report 1927, 1928*b*). It remains true, however, that no satisfactory vaccine for the active immunization of cattle has yet been devised (Waldmann and Reppin 1935). Formolized vaccines have not had much success in the field (Waldmann and Reppin 1935); but more recently Waldmann (1938) has described a promising vaccine in which the virus is adsorbed on to aluminium hydroxide and treated with 0·05 per cent. formol for 2 days at 25° C. Results of large field trials are still awaited.

Methods for dealing with an outbreak of foot-and-mouth disease vary in different countries. In Great Britain, the United States, and Scandinavia a rigorous policy of stamping out the disease by slaughter and disinfection is practised. In Germany the system known as Ring-Impfung is officially employed. This consists in isolating the affected farms, and giving all contact animals combined active and passive immunization, using for this purpose living virus and polyvalent hyperimmune serum. The result is a mild attack of the disease, which leaves behind it a more or less lasting immunity. At the same time animals on surrounding farms are given an injection of serum, the effect of which is to afford them some degree of passive immunity for about 10 days. The serum may, however, mask a mild attack, so that the infection of some animals passes unrecognized and may form a starting point for further spread. The whole area is isolated for 2–3 weeks. The merits of the two policies have often been discussed. There is no doubt that the slaughter method has proved, on the whole, satisfactory in countries where it has been thoroughly carried out. It is difficult to judge the value of the isolation and immunization policy without knowing how often and how long animals may remain carriers of the virus after an attack of the disease. Immune polyvalent serum made by hyperimmunization of cattle against the three main types of virus may be used prophylactically or therapeutically. Its value, however, is limited. It may protect cattle and pigs exposed for only 3 hours or so to contact infection, but not those exposed for 24 hours (Report 1937). In guinea-pigs the serum, though usually unable to protect completely against the disease, may prevent generalization of the infection.

Vesicular Stomatitis of Horses

This disease is similar in many respects to foot-and-mouth disease. It has been observed chiefly in South Africa and the United States, and is characterized by the development of vesicles on the oral mucosa, particularly on that of the tongue. Though the disease is primarily one of equines, cattle may become infected naturally; the lesions in cattle resemble those of foot-and-mouth disease, but are less extensive, and do not usually affect the feet. Intramuscular injection of cattle with the

vesicular stomatitis virus does not produce lesions, whereas injection with the foot-and-mouth virus does ; in horses, on the other hand, inoculation of the scarified tongue with the stomatitis virus produces lesions, whereas the foot-and-mouth virus does not. Pigs do not contract vesicular stomatitis naturally, but can be infected experimentally. The guinea-pig is susceptible to experimental inoculation with the stomatitis virus. According to Olitsky, Traum and Schoening (1928) there is no cross-immunity between foot-and-mouth disease and vesicular stomatitis in cattle. The causative virus differs from that of foot-and-mouth disease in being larger (70–100 mμ by ultrafiltration, 60 mμ by centrifugation, 80–100 mμ by ultra-violet photography), in being spherical instead of rod-shaped, in multiplying readily on the chorio-allantoic membrane of the developing chick embryo, and in having only one zone of pH stability, limited on the acid side by pH 4·5 (Galloway and Elford 1933, 1935, 1937, Elford and Galloway 1937, Burnet and Galloway 1937, Barnard 1937). There are at least two antigenic types.

Vesicular Exanthema of Swine

A disease bearing a close resemblance to foot-and-mouth disease was recognized in California about 1932, and was called vesicular exanthema of swine by Traum (1936). Outbreaks occurred irregularly, but on a generally increasing scale, till in 1939–40 the number of infected premises was 123 and the number of animals on these premises was over 220,000 (White 1940). It is an acute febrile disease, characterized by vesicles on the snout, lips, oral mucosa, tongue, and feet. The vesicles are 2–3 mm. and upwards in diameter. There is often considerable systemic disturbance, the temperature reaching 108° F. The animals suffer from varying degrees of lameness. Growth is seriously interrupted. The case mortality is low except in young sucking pigs, which may die either as the result of cessation of lactation in the nursing sow or of mechanical obstruction to respiration by the vesicles. Animals that recover develop a temporary immunity, which passes off in a few months' time. The disease spreads readily by contact. The incubation period is about 48 hours. Experimental inoculation is successful by the intradermal or intramuscular route. Clinically, the disease cannot be distinguished with certainty from foot-and-mouth disease, and reliance in the first place has to rest on animal inoculation. As will be seen from Table 188 the virus of vesicular exanthema of swine differs from that of foot-and-mouth disease in being pathogenic to horses, but not to cattle or guinea-pigs.

TABLE 188

Differential Susceptibility of Animals to Inoculation (Traum 1936)

Virus.	Swine.	Cattle.	Guinea-pigs.	Horses.
Foot-and-mouth . . .	+	+	+	−
Vesicular stomatitis . .	+	+	+	+
Vesicular exanthema . .	+	−	−	±

+ = susceptibility. ± = susceptibility less and irregular.

The susceptibility of the horse to vesicular exanthema is less than that of cattle, and may perhaps vary with different strains of virus. The British workers (Report 1937) failed in their efforts to infect horses with a strain of Californian origin.

The virus is antigenically different from any of the known types of foot-and-mouth virus, and there appears to be no cross-immunization between the two viruses. In control of the disease reliance is placed on rigid quarantine measures.

Virus III Infection of Rabbits

Virus III was the name given by Rivers and Tillett (1923, 1924*a*, *b*) to a filtrable virus encountered in rabbits during experimental work on chicken-pox. Injected intratesticularly into rabbits it produces a high fever and characteristic lesions in the cornea, testicles and skin ; within the epithelial and endothelial cells of these lesions acidophilic nuclear inclusion bodies are found, similar to those seen in herpes and varicella. Injected intracerebrally it sometimes gives rise to a meningo-encephalitis, not unlike that of herpetic encephalitis (Rivers and Stewart 1928). Frozen and desiccated, and kept in sealed tubes on ice, it retains its virulence indefinitely ; even after 15 months under these conditions it was still active. Its activity is also maintained for at least 6 weeks if infected testicular suspensions are mixed with equal amounts of glycerol, and stored on ice. It is destroyed by heat at 55° C. in 10 minutes. Rabbits injected with the virus develop an immunity to subsequent inoculation, which lasts for 6 months or more. The serum of immune rabbits contains antibodies capable of neutralizing the virus either *in vitro*, or locally in the rabbit's skin when the serum and virus are inoculated together. Attempts to confer passive immunity on rabbits, by intravenous injection of immune serum 24 hours previous to inoculation of the virus, proved negative. Rivers and Tillett found that about 15 per cent. of their young stock rabbits were refractory to infection with Virus III, indicating that they had suffered spontaneously from the disease. The same virus was met with in rabbits by Miller, Andrewes and Swift (1924). According to Andrewes (1929), it can be grown in tissue cultures prepared from adult rabbit testis. Typical intranuclear inclusion bodies are formed in these cultures. The symptoms of natural Virus III infection in rabbits are unknown. The virus is brought to light only by serial intratesticular passage, preferably at 4-day intervals. It may sometimes be present in rabbit tumours (Andrewes 1940), being carried as a so-called " passenger virus."

INFECTIOUS ECTROMELIA

This is a highly infective disease of mice, which was first described by Marchal (1930) at Hampstead. It occurs in an acute form characterized by the presence of visceral lesions, in a chronic form characterized by necrosis of the feet, and in a latent symptomless form. In the chronic form one of the feet becomes swollen and œdematous, and serous fluid escapes from the surface, forming minute scabs. The disease may retrogress, in which case the foot becomes gangrenous and sloughs off leaving healthy tissue behind ; or infection may spread to another foot, the tail, or the mouth, and lead to the death of the animal. In the acute form the animals die without any external lesions. Post mortem the liver may be dirty grey in colour, or it may be red and mottled due to the presence of small white focal areas of necrosis. The spleen is slightly enlarged, and may show large white areas, especially in the more chronic cases. There is often an excess of pleural fluid. It must be emphasized, however, that mice may die of ectromelia without showing any definite macroscopic lesions. Histologically, the chief characteristic is necrosis of the mesoblastic tissues, and the presence in the epithelial cells of the skin and

intestine of large acidophilic cytoplasmic inclusion bodies (see Figs. 234 and 235, p. 958). The disease can be readily transmitted to normal mice by contact, and by inoculation with infective material. Rats are susceptible, but develop only an "inapparent" infection (Burnet and Lush 1936*b*).

The causative agent is a virus, 100–150 mμ in diameter, which can be demonstrated microscopically in the liver and cutaneous tissues (Barnard and Elford 1931). It is widely distributed throughout the body. It is destroyed by exposure to 55° C. for 30 minutes, but withstands the action of 50 per cent. glycerol in the ice-chest for several months. It can be grown in tissue culture (Downie and McGaughey 1935), and on the chorio-allantoic membrane of the chick embryo (Paschen 1936). The case mortality of the disease is generally fairly high.

In diagnosis, the chronic foot lesions must be distinguished from those caused by *Actinomyces muris*. This organism can be cultivated directly on serum agar. One of the best methods of demonstrating the presence of the virus in a suspected mouse is to filter a suspension of the liver and spleen through sand and paper pulp, to add 0·5 per cent. phenol, to leave it in the ice-chest till it is bacteriologically sterile, and to inoculate it intraperitoneally into normal mice. If the virus is present, the animals will die within 4-6 days, and macroscopic lesions will be demonstrable in the liver.

Animals that recover from the disease have a substantial immunity. Normal animals can be vaccinated with considerable success by means of a formolized liver suspension (Greenwood and Topley 1936). For a study of the epidemic spread of the disease, see Greenwood and Topley (1936) and pp. 1256–1260.

CHAPTER 87

FILTRABLE VIRUS DISEASES—*Continued*

C. GROUP CHARACTERIZED BY LESIONS OF THE NERVOUS SYSTEM

ENCEPHALITIS

THERE are a number of diseases, many of them known to be caused by viruses, that affect the central nervous system and give rise to a picture of encephalitis, encephalomyelitis, or myelitis. The classification of these diseases is very difficult, and is generally made on the type of cell attacked. Since this is not a textbook of pathology, we do not wish to discuss the type of lesion produced in these diseases, particularly since there is still considerable disagreement among neuropathologists on this question. Those who wish for a classification along pathological lines may be referred to Rivers (1932) and Hurst (1936).

Fothergill (1941*a*) has suggested a classification based on the degree of neurotropism of the infecting virus: (*a*) caused by strictly neurotropic viruses, i.e. those which attack primarily nerve cells alone, such as the viruses of poliomyelitis, rabies, Borna disease, and pseudorabies; (*b*) caused by pantropic viruses, i.e. those multiplying not only in nerve cells, but in other types of cell, such as the viruses of St. Louis encephalitis, Australian X encephalitis, equine encephalomyelitis, and louping-ill; some of these diseases are insect-borne; (*c*) caused by viscerotropic viruses, such as vaccinia and mumps; these give rise more to a meningitis than to a true encephalitis. In addition, there are secondary types of encephalitis, such as post-vaccinal encephalitis, the causation of which is still unknown, but which are characterized pathologically by perivascular demyelinization.

In the account that follows we shall content ourselves with describing in sequence the more important diseases of man and animals in which the nervous system is affected.

Human Encephalitis

Encephalitis Lethargica.

This is a primary encephalitis, presumably of virus origin. The disease was first described by von Economo (1917) in Vienna, and was recognized in this country the following year. The highest year of incidence in England and Wales was 1924, when 5,039 cases were notified with 1,407 deaths. Since then the incidence has declined gradually, and in 1938 the number of registered deaths had fallen to 650. From post-mortem observations; however, it appears very doubtful whether more than a small proportion of the cases diagnosed as encephalitis lethargica are really examples of this disease. The true incidence is probably far lower than is indicated by the reported figures. *Epidemic hiccup* is regarded as a mild form of the disease (see MacNalty 1937).

Conflicting reports have been published on the ætiology of encephalitis lethargica. Much of the earlier work on the transmission of infection to animals was confused by the occurrence of a spontaneous disease of rabbits—meningo-encephalitis (see p. 1924)—and must be disregarded. Observations by Levaditi and Harvier (1922–23), Perdrau (1925*a*, *b*), da Fano and Perdrau (1927), and Gay and Holden (1933) suggest that the virus of encephalitis lethargica may be related to that of herpes, but this is little more than speculation. Though both McIntosh (1923) and McCartney (1924*b*) have reported the transmission of a fatal encephalitis to rabbits by the direct inoculation of brain suspensions from infected patients, it must be admitted that very little progress has been made in the study of this disease and its causation still remains obscure. (For a short summary of the experimental observations made on this disease the reader is referred to pages 1499–1501 in the 2nd edition of this book.)

St. Louis Encephalitis.—A very remarkable outbreak of encephalitis occurred in St. Louis, Mo., during the late summer of 1933. The epidemic started at the beginning of August and finished about the end of October. Rather over a thousand persons were attacked—an incidence of approximately 1 per 1,000 of the population. The case-mortality rate, which had an average of 20 per cent., showed a striking increase in relation to the age of the patient; thus, under 40 years of age it was less than 10 per cent.; in the 40–50 age group it was 12 per cent., in the 50–60 group 21 per cent., in the 60–70 group 38 per cent., in the 70–80 group 56 per cent., and in the 80–90 group 80 per cent. Over half the fatal cases died in the 1st week. The incubation period was not ascertained with certainty, but appeared to be from 4 to 21 days. Pathologically, the lesions differed in several respects from those in encephalitis lethargica, particularly in the more extensive involvement of the meninges and spinal cord, the more widespread distribution of inflammatory foci through the brain, and the greater frequency of degenerative changes in the nerve cells and of neuronophagia.

Cultures of the blood and spinal fluid were sterile. Attempts to transmit the disease to rabbits proved a failure, but successful results were obtained by Muckenfuss, Armstrong, and McCordock (1933) with *Macacus rhesus* monkeys. Combined intracerebral and intraperitoneal inoculation of human brain suspension was followed in 8–14 days by a steadily rising temperature, drowsiness, intention tremor, muscular weakness and inco-ordination of the extremities, and increased pressure of spinal fluid. Most of the animals were killed, and it is not known whether the disease would have proved fatal spontaneously. The changes in the nervous system observed post mortem were similar to those in the human disease. Only about 40 per cent. of monkeys proved susceptible, and after 5 passages, experiments with these animals were discontinued.

The disease was also shown to be transmissible to *mice* (Webster and Fite 1935*a*). After intracerebral inoculation with human brain suspension these animals develop in 3–4 days a condition characterized by hyperæsthesia, coarse tremors, convulsions, prostration, and death in 4–6 days. The disease can be passed indefinitely through mice. Other animals, with the possible exception of the mule, appear to be refractory. Mice can be immunized against intracerebral infection by subcutaneous or intraperitoneal inoculation with living virus (Webster 1938*b*).

The virus is about 20–30 mμ in size (Webster and Fite 1935*b*, Elford and Perdrau 1935). It has been cultivated by Syverton and Berry (1935) in a medium con-

taining minced living embryonic mouse brain, and by Harrison and Moore (1937) on the chorio-allantoic membrane of the developing chick embryo. It is present in great concentration in infected mouse brain; an intracerebral dose of even 3×10^{-8} gm. often proves fatal to mice. Mouse brain suspension remains virulent for at least 3 months when frozen; it withstands the action of 1 per cent. phenol for 25 days in the ice-chest, but is inactivated by 0·1 per cent. formol at room temperature in 12–18 hours (Brodie 1934*a*). Using the mouse protection test, in which the virus and the serum to be tested are mixed, incubated for 1 hour at 37° C., and inoculated intracerebrally into mice, it was found that the virus was neutralized by about 82 per cent. of sera from convalescent patients, but not by the serum of non-contacts or of patients who had suffered from herpes, encephalitis lethargica, or poliomyelitis (Webster, Fite and Clow 1935, Brodie 1934*a*). Wooley (1934), however, found that about 30 per cent. of sera from persons in different parts of the United States contained neutralizing bodies for the St. Louis virus. Neutralizing antibodies have also been found in Kenya, Congo, and possibly the Sudan, showing that the disease is not confined to the United States (Smithburn and Jacobs 1942). The virus is distinguished from the viruses of herpes and vaccinia by its failure to provoke a response in rabbits, and from those of Rift Valley fever, louping-ill, poliomyelitis, equine encephalitis, and mouse encephalitis by its effects upon monkeys and mice. It is closely related to the virus of Japanese B encephalitis and the West Nile encephalitis virus, but is said by Webster (1938*a*) and Casals (1944)—though Perdrau (1940) disagrees—to be antigenically distinguishable from it. The St. Louis virus is virulent for mice, but only weakly virulent for the monkey: the Japanese virus is virulent for mice, monkeys, and sheep.

The mode of spread of St. Louis encephalitis is not yet clear, but there is strong evidence to suggest insect transmission. Hammon and his colleagues (1942*b*, *c*) have isolated three strains of the St. Louis virus from mosquitoes—*Culex tarsalis* Coquillet—in the Yakima valley and have proved this insect to be capable of transmitting infection under experimental conditions. Diagnosis of the disease is aided by the complement-fixation test (Casals and Palacios 1941); antibodies appear in the blood within two weeks. (For a general account of the disease, see Report 1935.)

Japanese Encephalitis.—SYNONYM: *B encephalitis.*—In Japan several outbreaks of encephalitis have occurred during the past 80 years or so. They have been particularly common during the late summer months, and for this reason the disease is often referred to as "summer encephalitis." A large outbreak occurred in the summer and autumn of 1924, when there were over 7,000 cases with a fatality rate of 60 per cent. Another large epidemic, causing about 5,000 deaths, was witnessed in August and September 1935.

The causative virus was isolated and studied by Kasahara and his colleagues (1936*a*, *b*, 1937*a*, *b*) and by Taniguchi and his colleagues (1936). It is about 20–30 mμ in size (Yaoi *et al.* 1939); it can be cultivated in a medium of the Maitland type containing minced chick embryo brain (Kawakita 1939); it is avirulent to rabbits, but gives rise to a non-suppurative meningo-encephalomyelitis on intracerebral inoculation of mice, monkeys, and young sheep; it is neutralized by the serum of convalescent patients; and it can be distinguished by cross-neutralization tests from the virus of St. Louis encephalitis (Kawamura *et al.* 1936, Kasahara *et al.* 1937*a*, Webster 1938*a*) and from the West Nile virus (Casals

1944). Guinea-pigs are said by the Japanese workers (Kasahara *et al.* 1936*a*) to be susceptible to intratesticular inoculation, but they appear to be resistant to intracerebral inoculation (Webster 1938*a*).

In man the disease can be diagnosed during life by the demonstration of complement-fixing and of neutralizing antibodies in the patient's serum, and at autopsy by inoculation of brain tissue intracerebrally into mice. Histologically, degeneration of the Purkinje cells of the cerebellum is an outstanding lesion. There is some evidence that infection may be transmitted to man by mosquitoes —*Culex tritæniorhynchus* (see Fothergill 1941*a*). Neutralizing bodies to the Japanese B virus have been found in the blood of natives of the Sudan and Congo (Smithburn and Jacobs 1942).

Australian X Encephalitis.—A disease simulating the Japanese encephalitis occurred in Australia in 1917 and again in 1918. It had a high fatality rate—70 per cent. This so-called X disease broke out again in New South Wales in 1922 and 1926. The virus is readily transmissible to monkeys and to sheep, and the lesions to which it gives rise are very similar to those observed in sheep affected with louping-ill (see p. 1925). The X disease may possibly be contracted from sheep (Perdrau 1936).

Russian Spring-Summer Encephalitis.—In 1937 cases of human encephalitis were recognized by Chumakov and Gladkikh (1940) occurring particularly among wood-cutters in thickly forested areas of the Soviet Far East. The disease occurs in the spring and summer months, and is transmitted by the bite of the tick, *Ixodes persulcatus* Schulz. Wild rodents appear to constitute a reservoir of infection in endemic areas. A virus was isolated from the brain of fatal cases, which the Russian workers looked upon as resembling the virus of Japanese B encephalitis. According to Casals and Webster (1944), who studied three strains, and to Casals (1944), it is very similar to, though not identical with, the virus of louping-ill (see p. 1925).

West Nile virus Encephalitis.—Smithburn, Hughes, Burke and Paul (1940) described the isolation of a virus from the blood of an African woman who was suffering only from slight fever, but who subsequently developed neutralizing antibodies in her serum. The agent was designated the West Nile virus, from the district in which it was encountered. Mice and monkeys inoculated intracerebrally developed encephalitis, and degenerative changes were found in the Purkinje cells of the cerebellum recalling those produced by the louping-ill virus. Smithburn (1942) compared the West Nile virus with the viruses of St. Louis and of Japanese B encephalitis. All three were found to be related to each other, but to be distinguishable by cross-neutralization tests. Human sera that neutralized the West Nile virus failed to neutralize either of the other two, but antisera to the St. Louis and Japanese B viruses partly neutralized the West Nile virus. The relationship of this virus to the virus of louping-ill has not yet been determined. It may be noted, however, that the West Nile virus is estimated to be 21–31 mμ in diameter, whereas the louping-ill virus appears to be only 15–20 mμ.

Encephalomyelitis due to Equine virus.—As its name implies, equine encephalomyelitis is essentially a disease of horses (see below). During the late summer and early autumn of 1938 there was a large outbreak in the United States, and human cases of the disease were recognized for the first time. Diagnosis of infection

TABLE 189

PRIMARY ENCEPHALOMYELITIS OF HUMAN BEINGS. (Modified from Webster 1941*b*)

Disease.	Reservoir.	Mode of Transmission.	Size of Virus mμ	Susceptibility of Animals to Intracerebral Inoculation.						Remarks

with the eastern type of virus was made by Fothergill, Dingle, Farber and Connerley (1938) and by Webster and Wright (1938), and with the western type of virus by Howitt (1938*b*). The disease occurred in rural areas, and affected particularly infants and young children, in whom it caused a high mortality. The virus can sometimes be demonstrated in the blood (Howitt 1939) and in the cerebrospinal fluid (Fothergill, Holden and Wyckoff 1939) during life. After death it may be isolated from the brain by intracerebral inoculation of mice. Neutralizing antibodies are often present in the blood serum and the cerebrospinal fluid of convalescent patients (Howitt 1941, Buss and Howitt 1941). Healthy contacts who have been exposed to infection may also show neutralizing antibodies (Mitchell and Pullin 1943). Diagnosis during life may be made by the demonstration of complement-fixing and neutralizing antibodies in the patient's serum (Casals and Palacios 1941, Casals 1941, Howitt 1943). Infection is probably carried by mosquitoes—*Culex tarsalis* Coquillet (Hammon *et al.* 1942*a*, *b*). Besides the disease due to the eastern and western types of virus, laboratory infections have been described with the Venezuelan type (Casals *et al.* 1943).

Bwamba Fever.—A mild non-fatal disease, apparently caused by a virus producing nervous symptoms in mice, was encountered in African natives by Smithburn, Mahaffy and Paul (1941) during a yellow fever survey in the Western Province of Uganda and was named by them Bwamba fever. Clinically, the disease was characterized by a sudden onset with fever, headache, and pain in the lumbar region, mild conjunctival injection and a skin rash. The fever lasted for 2–5 days, the headache and backache for 2 or 3 days longer. Convalescence was rapid and complete. The disease did not appear to be highly contagious. A virus could be demonstrated in the blood by intracerebral inoculation of mice, and could be carried over from one mouse to another by injection of brain tissue. After intracerebral injection symptoms of nervous excitement appeared in about 4 days, and the animals generally died a day later. At post mortem there was a variable degree of hyperæmia and œdema of the brain. Microscopically, widespread degenerative changes were seen in the pyramidal cells of the cortex, together with single or multiple acidophilic intranuclear bodies resembling inclusions. Infection did not spread from mouse to mouse by contact, even though the animals could be infected by intranasal inoculation. Monkeys developed a non-fatal febrile illness when injected intracerebrally. Guinea-pigs and rabbits proved resistant. The virus passed through a Seitz filter. Judged by experiments with gradocol membranes its size was between 113 and 150 mμ. It could be readily preserved by drying from the frozen state, but a saline suspension kept in the ice-chest proved innocuous within 13 days. It was destroyed by exposure to heat at 50° C. for 30 minutes. Antibodies specifically neutralizing the virus were demonstrated in convalescent human and monkey serum. So far as could be ascertained, the 9 strains of virus that were isolated appeared to be antigenically identical.

Semliki Forest Virus.—Under this name Smithburn and Haddow (1944) and Smithburn, Mahaffy and Haddow (1944) have described a virus isolated from a group of *Aëdes abnormalis* mosquitoes caught in the Semliki forest of Western Uganda. It killed mice when inoculated by various routes, but was fatal to guinea-pigs, rabbits and *rhesus* monkeys only on intracerebral inoculation. In the brain it produced lesions resembling those caused by the equine encephalomyelitis viruses. By neutralization tests it was found to differ from other encephalitis viruses, including the West Nile virus, though it was not compared with the virus of Russian spring-summer encephalitis. It also appeared to be smaller in size than any of these viruses. Whether it is pathogenic to human beings is not known, but neutralizing antibodies were found in a proportion of human sera collected in the neighbourhood. It is suggested that the red-tail monkey, *Cercopithecus nictitans*, may form one of the natural reservoirs of the virus.

Ascending Myelitis. " B " virus and herpes virus.—Sabin and Wright (1934) recorded a human case of acute ascending myelitis, associated with focal necroses in the viscera, following the bite of an apparently normal *Macacus rhesus* monkey. By the inoculation of rabbits a strongly neurotropic filtrable virus was demonstrated in the patient's brain, cord and spleen. In monkeys the neurotropic tendency was not so evident. Intravenous inoculation of these animals was followed by a generalized disease not unlike that caused by vaccinia, and accompanied by a rash on the face, buccal mucosa, and conjunctiva (Sabin 1934). Besides rabbits and monkeys, guinea-pigs are also susceptible to experimental inoculation. The virus, which is usually referred to as the " B " virus, can be cultivated on the chorio-allantoic membrane of the developing chick embryo (Burnet, Lush and Jackson 1939*a*). Infection appears to be endemic in monkeys, in which neutralizing antibodies can often be demonstrated; morbidity and mortality in these animals, however, are very low.

Primary myelitis may follow the intravenous inoculation of *herpes* virus into rabbits (Koppisch 1935, Doerr and Hallauer 1936). We shall subsequently have occasion to refer to cases of acute ascending myelitis of the Landry type caused by the virus of rabies.

Burnet, Lush and Jackson (1939*b*) have drawn attention to the similarity between the B virus, the herpes virus, and the pseudorabies virus. All produce intranuclear inclusion bodies; all are predominantly but not strictly neurotropic; all may appear in the blood after inoculation into a distal part; but they invade the central nervous system, not like louping-ill, equine encephalomyelitis and some other viruses by way of the blood, olfactory mucosa, and olfactory bulbs, but by the peripheral nerves; all tend to produce death in experimentally inoculated animals at a time when little virus is present in the brain; and all are comparatively innocuous to hosts in which they naturally cause endemic infection, but are highly fatal to other animals.

Secondary Encephalitis.—We have already (p. 1894) drawn attention to the encephalitis that occasionally follows vaccination against smallpox, and have discussed its ætiology. Similar cases of encephalitis sometimes occur during convalescence from other diseases such as measles, varicella, mumps, yellow fever, and influenza. The most striking characteristic of all these cases is the occurrence of perivascular demyelination—a lesion which is not usually met with in primary encephalitis. Whether the production of secondary encephalitis is due to the virus causing the primary disease, or to a different virus lying latent in the tissues, or is a purely degenerative condition not determined by a virus at all, remains a subject for debate (see McIntosh 1928, McIntosh and Scarff 1928, Greenfield 1930, Rivers 1932, Ledingham 1935, Hurst 1936).

For a description of the clinical and pathological manifestations of the various types of encephalitis in human beings, the reader is referred to the monograph by Neal (1942).

Encephalitis in Animals

Borna Disease. Endemic Encephalomyelitis of Horses, Cattle and Sheep.

Borna disease is the name given to an infectious encephalomyelitis of horses. The name " Borna " is derived from the locality in Saxony where a severe epizootic occurred during the years 1894–96. The disease is widely distributed, and may occur in epidemic form with a mortality sometimes reaching 90 per cent. A similar

encephalomyelitis is likewise observed in cattle and sheep. Histologically, lesions are found in the central nervous system and in the peripheral nerves, and characteristic inclusions (Joest-Degen intranuclear corpuscles) are observed in the large ganglion cells of Ammon's horn. The disease is due to a filtrable virus, which appears to be the same in all three species of animal. According to Elford and Galloway (1933*b*) it is about 85–125 mμ in diameter. The virus is resistant to glycerol, but sensitive to desiccation, ultra-violet light, and heat. Inoculated intracerebrally into rabbits it gives rise after an incubation period of 15 to 50 days to a disease characterized by cerebral symptoms and proving fatal in 5 to 17 days. The virus produces lesions in the central nervous system, and makes its way down the peripheral nerves, in which it sets up an interstitial neuritis. Monkeys, guinea-pigs, and rats are also susceptible. Rabbits may be immunized against the disease by the inoculation of suitably attenuated virus into the brain; sometimes immunity is produced by multiple inoculations subcutaneously of large quantities of formolized vaccine. There is some evidence that the Borna virus is related to the virus of poliomyelitis. (For an excellent review of the disease, together with an account of original work, see Nicolau and Galloway 1928.)

Encephalomyelitis of Horses.—This is an endemic disease of the United States and Canada, which has, however, been recognized in parts of South America. It resembles the Borna disease of Europe, differing from it in the histological character of the lesions and in the type of the causative virus (Hurst 1934, Howitt 1935). In the United States it has been observed mainly along the Atlantic seaboard and in California. The disease occurs in the late summer and autumn. The eastern type is seen in salt marshes, the western type in river valleys. There is strong evidence to suggest that the disease is spread by insects (for references see Fothergill 1941*b*). Kelser (1933) showed experimentally that infection could be transmitted by the mosquito, *Aedes ægypti*. More recently the western type of virus has been demonstrated under natural conditions in another mosquito, *Culex tarsalis* Coquillet (Hammon *et al.* 1942*b*, *c*). In 1937 and 1938 there was a very large outbreak of the disease, several thousand horses dying. At the same time, a considerable mortality was observed among pigeons (Fothergill and Dingle 1938) and pheasants (Tyzzer, Sellards and Bennett 1938); from both of these birds the eastern type of virus was isolated. A field study by Hammon and his colleagues (1942*a*) in the Yakima valley revealed the presence of neutralizing bodies for the western type of virus in the sera of about 50 per cent. of domestic birds and 35 per cent. of domestic mammals studied, and of about 20 per cent. of wild birds and 8 per cent. of wild mammals. It would appear therefore that the disease is endemic in animals and birds, and that, as suggested by Tenbroeck, Hurst and Traub (1935), the horse is not the primary reservoir of infection. It is of interest to inquire how an epidemic disease of the central nervous system can be spread by a blood-sucking insect. The answer appears to be that, after gaining access to the horse, the virus invades the blood stream and multiplies in the viscera. After this first pyrexial stage of the disease, the virus disappears from the blood stream and reaches the central nervous system—apparently by way of the cranial nerves. The horse is therefore infective for the mosquito during only a brief period. This is an additional reason for believing that the virus has its habitat in other animals.

The cause of the western type of the disease was found by Meyer, Haring and Howitt (1931) to be a filtrable virus. A similar virus, differing from it immuno-

logically was later shown by Ten Broeck and Merrill (1933), Howitt (1935), Records and Vawter 1935) and Shahan and Giltner (1935) to be responsible for the eastern type. Both viruses are estimated to be about 20–35 mμ in diameter (Bauer *et al.* 1935, Tang *et al.* 1937), though Sharp and his colleagues (1943) give a figure of about 50 mμ. They can be grown readily in tissue culture and on the chorio-allantoic membrane of the developing chick embryo. They remain viable in 50 per cent. glycerol in the ice-chest for a long time, but are readily destroyed by formalin. The eastern type is said to be more pathogenic than the western for guinea-pigs and rabbits, but both have a wide range of pathogenicity. The Argentine type of virus studied by Howitt (1935) appears to be identical with the western type, but the Venezuelan type, described by Beck and Wyckoff (1938) and Kubes and Ríos (1939), is immunologically distinct. Howitt (1938*a*) likewise found a Russian strain, labelled Moscow 2, to be immunologically distinct from the other viruses. The Russian virus, however, differs in important respects from the viruses of equine encephalomyelitis met with in the western hemisphere. It is much larger, having a diameter of 85–130 mμ (Lazarus and Howitt 1937), and has not so far been grown in tissue culture or in the chick embryo. In both these respects it resembles the virus of Borna disease, from which it seems to be distinguished mainly by its antigenic structure and its greater invasive power for animals (Howitt 1938*a*). Since morphology must be one of the primary characters on which classification is based, it would seem wise to regard the Russian virus as allied to the Borna rather than to the American group of viruses.

In protection against equine encephalomyelitis inoculation with a formolized chick embryo vaccine, using the technique of cultivation described by Higbie and Howitt (1935), appears to be hopeful (see Eichhorn and Wyckoff 1938, Fothergill 1941*b*).

Encephalitis of Foxes.—This disease is endemic in certain parts of the United States, and at times assumes epidemic proportions. It is caused by a filtrable virus which invades the blood, probably through the respiratory mucosa, and may be demonstrated in various tissues. Clinically the disease is characterized by anorexia, hyperexcitability or lethargy, convulsions, paralysis, and not infrequently by death. Pathologically, hæmorrhages in the brain and cord and in the viscera constitute the most striking feature of the disease; perivascular infiltration with round cells is common in the cerebral nervous system, and the meninges are usually involved. Characteristic intranuclear inclusion bodies are found in the ependymal and endothelial cells of the central nervous system. The disease can be reproduced by intramuscular, intranasal, or intracranial inoculation of young foxes with homogenized brain and spinal cord. Unlike the natural disease, which seldom has a case mortality exceeding 20 per cent., the experimental disease is fatal in about 70 per cent. of cases. Infection can also be transmitted to dogs, though with some irregularity. (For an account of the disease see Green *et al.* 1930, 1931, 1933, 1934, 1936, Green 1931, 1936, Green and Shillinger 1934.)

Encephalomyelitis of Mice.—This disease has been described by Theiler (1937) in the United States, Gildemeister and Ahlfeld (1938) in Germany, and Iguchi (1939) in Japan. It is characterized by flaccid paralysis of the limbs and sometimes convulsions. Infection can be transmitted by intracerebral, intranasal and intraperitoneal inoculation. After intracerebral inoculation of mice there is an incubation period of 5–30 days. Flaccid paralysis then develops, usually affecting the fore limbs first, but being more severe in the hind limbs. Death

usually follows 5–10 days after the onset of paralysis, but some animals survive and remain carriers for a time. Paralysed and carrier mice are resistant to a second intracerebral inoculation. There is evidence that immunity depends on the presence of neutralizing antibodies in the blood serum. Histologically, perivascular cellular infiltration is found throughout the central nervous system; there is acute necrosis of the ganglion cells, particularly in the anterior horn, followed by neuronophagia. No inclusion bodies appear to have been demonstrated yet.

The virus is one of the smallest known—9 to 13 mμ—resembling in this respect the virus of poliomyelitis. It is readily destroyed at temperatures above 50° C., and by 20 per cent. alcohol, but is resistant to ether and to 50 per cent. glycerol (Theiler and Gard 1940). It is non-pathogenic for *rhesus* monkeys and for rabbits. Infection seems to be widespread in colonies of mice, though only a small proportion of animals develop the characteristic disease. According to Gard (1944), infection may perhaps be activated by organisms of the *Salmonella* and other groups that give rise to enteritis. By the time they are 4 weeks old nearly every mouse in a colony in which the disease is endemic appears to be infected. The virus is present in the mucosa of the stomach and intestine, the mesenteric lymph nodes and the fæces of young mice, but can no longer be found after the animals reach the age of 6 months. By this time immunity has been acquired (see Olitsky 1939*b*, 1940, Theiler and Gard 1940).

Infectious Encephalomyelitis of Chickens.—This disease, which is sometimes referred to under the name of "epidemic tremor of chickens," was reported by Jones (1934) in New England. It is characterized by tremor, most noticeable in the head and neck, and progressive ataxia, either or both of which may be present in a single bird. Young chickens are mainly attacked, the usual age of onset being about 3 weeks. In commercial flocks the morbidity ranges from 5 to 50 per cent. In severe outbreaks about half the chicks may die; death is due to inanition caused by the progressive ataxia. Histologically, focal collections of glia cells, perivascular infiltration, and degeneration of nerve cells, especially of the Purkinje cells in the cerebellum, are found in the central nervous system. No inclusion bodies have yet been demonstrated. The disease can be reproduced in young chicks by intracerebral inoculation of brain and cord from affected birds. The incubation period of the experimental disease is usually 2–4 weeks; death follows about a week after the onset of symptoms (van Roekel *et al.* 1938). The infective agent is probably fairly large, since it can pass through a Berkefeld N but not a W filter. According to Olitsky (1939*a*), birds that recover from the disease are immune, and neutralizing antibodies can be found in their blood serum.

Meningo-encephalitis of Rabbits.—Though this is not a virus disease, it may be conveniently considered here, since it is of considerable laboratory importance and has in the past caused much confusion, especially in work on encephalitis lethargica. In 1922 Oliver described a spontaneous chronic meningo-encephalitis affecting 20 per cent. of her normal stock rabbits. Similar lesions in a few animals had been observed a few years previously by Bull (1917), while working on streptococci isolated from poliomyelitis. In this country the disease was described independently by Twort (1922) and Twort and Archer (1923), who likewise met with it while investigating a different problem. McCartney (1924*a*) found that 55 per cent. of the stock rabbits at the Rockefeller Institute in New York were infected.

The disease may occur in epizootics; symptoms are usually absent. Histologically, in the brain there are infiltrations with lymphocytes and plasma cells, occurring around the vessels, in the meninges, and in the cerebral substance itself, where the cells may form local aggregations or be widely diffused. In 15 per cent. of the rabbits there are, in addition, focal areas of necrosis, consisting of a necrotic centre surrounded by epithelioid cells, around which is a layer of mononuclear cells. In the centre of these necrotic lesions, there may be rounded or oval cyst-like bodies, containing numbers of small spherical, spindle- or pear-shaped particles, similar to those described by Levaditi under the name of *Encephalitozoon cuniculi*. These bodies generally consist of a thin structureless membrane, and a protoplasmic mass with regularly distributed chromatin particles; on careful examination, it is found that the protoplasmic mass really consists of small spindle- or pear-shaped portions, each of which is provided with a particle of chromatin. This parasite appears to be a microsporidium belonging to the *Sporozoa*; it has been found both in the brain and in the kidney lesions that occur in the disease. Under natural conditions this spontaneous meningo-encephalitis is spread by cage infection; experimentally it can be transmitted by inoculation of nervous substance and the sedimented urine of infected animals. The parasite was described by Wright and Craighead in 1922, before Oliver had drawn attention to the spontaneous disease to which it gives rise. Cowdry and Nicholson (1924) have found a similar parasite in spontaneous encephalitis of mice (see also Pette 1928).

A similar disease has been reported by Markham (1937) in guinea-pigs.

Louping-ill.—This disease is an encephalomyelitis of sheep characterized by cerebellar ataxia. The word " louping " is derived from an old Norse word meaning " leap," and refers to the peculiar gait of the animals which spring up and down when moving forwards. The disease seems to be limited to the border counties of England and Scotland and to the Western Highlands. It occurs in early spring, and is commonest on farms where there is rough hill grazing (Pool 1934). It has been studied mainly by workers in Scotland, who have shown (1) that the disease is caused by a virus which invades the blood stream and sometimes, but by no means always, affects the nervous system; (2) that infection is carried by the tick *Ixodes ricinus* L., which is habitually present on louping-ill pastures; (3) that infection can be transmitted by intracerebral inoculation to sheep, pigs, and mice; (4) that the disease is often abortive; (5) that recovery from the overt, abortive, or latent disease is followed by a substantial degree of immunity; (6) that some protection can be afforded by the use of formolized vaccine inoculated subcutaneously; (7) that destruction of the Purkinje cells in the cerebellum is one of the characteristic pathological lesions of the disease; and (8) that an entirely different disease —tick-borne fever—suspected to be of rickettsial origin, sometimes co-existed with louping-ill and increased its severity (see Pool *et al.* 1930, Alston and Gibson 1931, Brownlee and Wilson 1932, Gordon *et al.* 1932, MacLeod and Gordon 1932, Gordon 1934). The disease may also be transmitted to monkeys (Hurst 1931*a*) and to field voles (Findlay and Elton 1933). Both mice and monkeys can be infected by intranasal as well as by intracerebral inoculation (Elford and Galloway 1933*a*, Galloway and Perdrau 1935). The virus can apparently reach the central nervous system from the nose without entering the blood stream. Rivers and Schwentker (1934) appear to have observed the disease in laboratory workers. Clinically the picture was that of an influenza accompanied by encephalitis. Recovery occurred, and neutralizing bodies were demonstrated in the patients' sera. The virus, however, was not isolated. According to Elford and Galloway (1933*a*), the causative virus is about 15–20 mμ in diameter. Even after 40 mouse passages, it still remained infective for sheep.

POLIOMYELITIS

Poliomyelitis is principally a disease of young children, which occurs sporadically and epidemically. In the northern hemisphere epidemics are commonest in the late summer and early autumn months, the maximum incidence of the disease being reached in August or September. During the present century the United States of America has experienced three major outbreaks—in 1916, 1931 and 1943. The disease resembles cerebrospinal meningitis in attacking only a small proportion of the population; though, as in meningitis, there is reason to believe that infection of a considerable proportion of the population occurs without giving rise to clinical evidence of disease. The case mortality of the declared disease is usually about 10–15 per cent., but it may reach a figure of even 40 per cent. The proportion of cases that show residual paralysis is difficult to estimate, because there is an increasing tendency among clinicians to diagnose the disease in the pre-paralytic stage. In this way a considerable number of abortive cases are included that do not develop paralysis at all. Probably not more than about 15–40 per cent. of the total cases show residual paralysis, and in many of these partial or even complete restoration of function ultimately occurs. Males are affected more often than females.

In the past poliomyelitis has been largely a disease of infancy and early childhood, but of late years the older age groups have been progressively more and more affected (see Burnet 1940). Thus, in the Danish outbreak of 1934 no fewer than 33·2 per cent. of the cases were in persons aged 15 years or more (Jensen 1935). The incubation period is not known with certainty, but is believed to be about 7–14 days. Multiple cases in families are uncommon, and when they do occur are usually more or less simultaneous (Aycock 1941). The disease has been increasing in prevalence during the past 40 years or so; and, though this country has suffered but little, severe epidemics have occurred in other parts of Europe and in North America. The incidence diminishes as the tropics are approached.

The distribution of the cases in an epidemic is irregular. Wickman (1907), who investigated the big Swedish epidemic, found that the disease spread along the lines of communication, railways, roads, and so on. He brought evidence to show that infection was spread by carriers and by cases. Since it has been found that perfectly healthy persons may carry infection, and that patients may be infective in the incubation period, as well as for a week or two after the commencement of the disease, it is obvious that the prevention of infection by the isolation of cases or quarantining of contacts is not likely to be successful. The disease rarely becomes epidemic in schools or institutions, but it may attack a rural community in a characteristically epidemic form. Thus in the little village of Stokes Rivers, in Devonshire, 45 persons were attacked out of a total population of 119.

Mode and Route of Infection.—The mode of infection is still obscure. There is a mass of evidence pointing in different directions—one to the respiratory, the other to the alimentary route.

Largely under the influence of Flexner, who studied the experimental disease in *rhesus* monkeys, the prevailing belief for many years was that infection was carried by naso-pharyngeal droplets; that the virus invaded the terminal processes of the olfactory nerves—the so-called olfactory hairs; and that it spread along the axis cylinders to the brain, and thence to the anterior horn cells of the cord, where the chief lesions are produced.

The evidence in favour of the intraneural passage of the virus from the periphery to the centre is strong (Fairbrother and Hurst 1930, Hurst 1930, 1936, Faber and Gebhardt 1933, Leake 1935, Bodian and Howe 1941*a*, *b*); but the evidence in favour of nasal infection in human beings is much less convincing. It is true that the virus has been demonstrated occasionally in the nasopharynx of patients suffering from the typical and from the abortive form of the disease, and occasionally of healthy carriers; but observations on human beings who have died of the disease suggest that the olfactory bulbs are infected in only about 10 per cent. of cases (Burnet 1940, Kessel *et al.* 1941), or even less (see Howe and Bodian 1941*b*). On the other hand, the virus is frequently present in the pharyngeal tissues, the intestinal contents, and the stools, particularly of children (see Kling, Pettersson and Wernstedt 1912, Sawyer 1915, Trask, Vignec and Paul 1938, Trask, Paul and Vignec 1940, Trask and Paul 1941, Sabin and Ward 1941, Kessel *et al.* 1941, Langmuir 1942) It appears to be far commoner in the intestinal contents than in nasal washings, suggesting that multiplication may occur in the alimentary tract itself. Kessel and his colleagues (1941), for example, isolated the virus from the stools of 20 per cent. of patients, but not once from 139 nasal washings. Sabin and Ward (1941), who record similar findings, failed also to show the presence of the virus in the saliva. The virus can be demonstrated in the fæces, not only of patients, but of contacts during an outbreak. Thus, Langmuir (1942) found it in the fæces of 4 out of 5 cases and of 20 out of 27 intimate contacts. The studies of Pearson and his colleagues (Pearson and Rendtorff 1945, Pearson *et al.* 1945) seem to show that the virus is restricted very largely to cases and close contacts. Thus, during an epidemic at Forth Worth, Texas, in 1943 the virus was demonstrated in the stools in 6 out of 8 households containing 27 familial contacts, in 8 out of 45 households containing 80 non-familial contacts, and in only 2 out of 127 households containing 374 non-contacts. Similarly, Kessel and Moore (1945), who examined tonsils and stools from non-contacts during an inter-epidemic period, isolated the virus from only 5 out of 136 persons studied. It is present in the spinal cord in fatal cases, but is never found in the blood, the cerebrospinal fluid, or the urine.

The interpretation of these findings is difficult. We must try to relate them to the epidemiological picture. The evidence pointing to the alimentary route of infection is briefly that the disease occurs in the summer and early autumn months; that the virus appears to be commoner in the alimentary tract than in the nose; that it may persist for a long time in convalescent and healthy carriers (see Trask and Paul 1941); that it is often present in sewage (Paul, Trask and Gard 1940, Paul and Trask 1941, 1942); and that it has been isolated from flies (Trask, Paul and Melnick 1943). In addition, *cynomolgus*, but not *rhesus*, monkeys can be infected by feeding; outbreaks of milk-borne infection have been described (see Aycock 1941); and several cases of the disease have been reported after tonsillectomy, though nearly always of the uncommon bulbar form. On the other hand, the disease does not behave epidemiologically like a water-borne disease (see Maxcy 1943); and milk-borne infections are not uncommon in diseases, such as scarlet fever and diphtheria, that are normally transmitted by droplets. The natural spread of infection in an epidemic is far more like that of a respiratory infection, such as cerebrospinal meningitis, though the seasonal incidence is different. Burnet (1940) points out that in the Victorian outbreak of 1937–38 there was clear evidence of the spread of infection by patients—especially abortive cases—and that the only likely mode of transference was by droplet infection. He showed that *cynomolgus* monkeys could be infected by simple swabbing of the pharyngeal mucosa with infected material (see also Faber, Silverberg and Dong 1944). He concludes that under natural epidemic conditions infection usually occurs by inhalation or ingestion of contaminated saliva from an infected child, and that

the virus gains access to the brain by the cranial nerves supplying the pharyngeal mucosa. Sabin (1941), influenced more by the frequent presence of the virus in the fæces and by his failure to find it in the saliva, believes that the virus multiplies in the walls of the pharynx and small gut and invades the medulla or spinal cord by the cranial nerves or by the sympathetic and parasympathetic nervous systems. Bedson (1943) likewise favours the alimentary route of infection.

It is impossible to come to any final conclusion on the usual mode of infection of human beings. On the whole, the evidence points towards the tonsillo-pharyngeal mucosa as being one of the commonest sites of invasion, and to infection being generally air-borne rather than food-borne; but whether the infective air-borne material consists of infected droplets expelled from the nose and mouth or of dust contaminated by fæces is still open to question. Insect-borne infection, which has been suggested, is improbable, mainly because the virus has never been demonstrated in the blood stream, though flies might, of course, become contaminated from fæces and sewage.

Transmission to Animals.—Poliomyelitis is readily transmissible to monkeys. Other animals, with the exception of the cotton rat and the white mouse, which may be infected by specially adapted strains, are insusceptible.

Landsteiner and Popper (1909) were the first to transmit the disease to monkeys; they injected the spinal cord from two fatal cases intraperitoneally into two monkeys. One animal became paralysed in the lower extremities, and died on the 6th day after inoculation; the other was killed on the 19th day. At necropsy, lesions of the spinal cord, similar to those in man, were found in both monkeys. Later in the same year, Flexner and Lewis (1910), using cords from two human cases, succeeded in infecting monkeys (*Macacus rhesus*) by intracerebral, subcutaneous, intraperitoneal, intravenous, intrathecal and intraneural inoculation; intratracheal inoculation and feeding proved unsuccessful. They were able, in addition, to carry over the disease from monkey to monkey by subdural injection of cord suspensions. Flexner and Lewis showed that the disease could be produced, not only by crude cord suspensions, but also by Berkefeld filtrates of these suspensions, and by filtrates of nasopharyngeal washings. Intranasal instillation is also successful (see Flexner 1935), and with some strains intracutaneous inoculation (Trask and Paul 1936).

The disease in *monkeys* is similar to that in human beings. After intracerebral inoculation, there is an incubation period of about 6 to 10 days. During the prodromal period the monkey becomes excitable, the fur is ruffled, there is a high-pitched staccato cry, and the animal easily becomes tired. Within a few hours ataxia develops, accompanied by tremor of the arms, legs or head. The ataxia rapidly merges into a flaccid paralysis, which extends to practically all the muscles of the body except those of the tail, jaws and diaphragm. The temperature drops to subnormal, the animal becomes weaker, and dies within 3 days after becoming prostrate (Amoss 1928). At necropsy, the lesions are similar to those in human beings, and may be briefly summarized as follows: (1) The lesions are chiefly in the grey matter of the cord; the brain is only slightly affected. (2) There is a marked perivascular sheath infiltration, and a more diffuse infiltration of the grey matter of the cord; the cells consist chiefly of lymphocytes, with a fair proportion of polymorphs and a small number of large cells with clear nuclei; plasma cells and lymphoblasts are rare. (3) There is marked degeneration of the ganglion cells of the grey matter; all stages of cellular degeneration, from a slight chromatolysis to complete neuronophagia can be seen. (4) Hæmorrhages are usually present in the grey matter of the cord (McIntosh

and Scarff 1928, Hurst 1929). Characteristic intranuclear inclusion bodies have been described in the nerve cells of fatal human cases, though in monkeys they are less easy to demonstrate owing to the very rapid necrosis that these cells undergo (Hurst 1931*b*).

Though Flexner, using *M. rhesus* monkeys, was unable to set up the disease by feeding, Kling, Levaditi and Hornus (1934) showed that *M. cynomolgus* monkeys were susceptible. The results of these workers were confirmed by Lépine and Sédallian (1939) and Vignec, Paul and Trask (1939). Chimpanzees can likewise be infected by the mouth, even after bilateral section of the olfactory tract (Howe and Bodian 1941*a*). Aisenberg and Grubb (1943) record the successful production of poliomyelitis in *rhesus* monkeys by instillation of infective material into the pulp canal of three anterior teeth. The cavities were immediately sealed to prevent escape of the virus. After 8 days all four legs were paralysed. At post mortem, lesions were found in the Gasserian ganglions, suggestive of a direct nervous spread to the brain.

Armstrong (1939) showed that the Lansing strain of poliomyelitis virus, which had been passed through monkeys, could be transmitted by intracerebral inoculation to *cotton rats* (*Sigmodon hispidus hispidus*); and Jungeblut and Sanders (1940) showed that, after becoming adapted to the cotton rat, the strain could be passed on to *white mice*. The incubation period in cotton rats is 3–8 days, in white mice 2–10 days. Paralysis of one or more legs is first observed and death occurs from respiratory failure in 24–48 hours. Recovery is uncommon (Armstrong 1941).

Properties of the Virus.—Flexner and Noguchi (1913) described the cultivation of minute globoid bodies, 0·15–0·3 μ in diameter, in an ascitic fluid rabbit kidney medium, and brought evidence to show that these bodies constituted the causative agent of the disease. The balance of evidence, however, is definitely against this conclusion (see Fairbrother 1929). More recent work has shown that the virus is probably much smaller—12–17 mμ according to Theiler and Bauer (1934), 8–12 mμ (Elford *et al.* 1935). It has proved very difficult to grow in culture. Sabin and Olitsky (1936), however, appear to have been successful in cultivating it in the presence of nervous tissue removed from human embryos. It is very susceptible to heat, being destroyed in 30 minutes by exposure to a temperature of 45°–50° C. It is killed rapidly by ultra-violet light (Jungeblut 1937). On the other hand, it is resistant to freezing, drying, X-rays, sonic vibration, and numerous protoplasmic poisons (see Jungeblut 1937). It survives in water for a month in the light and 3–4 months in the dark. It remains active in fæces at ice-box temperature for several months, but dies out in a few days in sewage. It withstands 1 per cent. phenol and 15 per cent. ether for several months at 0° C. (Paul, Trask and Gard 1940, Paul and Trask 1942). In 50 per cent. glycerol it can be preserved for 4 to 6 years (Amoss 1928). Little is yet known about its antigenic structure, but cross-neutralization tests carried out with the sera of convalescent human beings and monkeys show that several immunologically distinct types of virus exist. The serum of monkeys convalescent from infection with one type may fail to protect against infection with another, and convalescent monkeys immune to re-inoculation with the homologous type can be re-infected with a heterologous type (see Burnet and Macnamara 1931, Southby and McKie 1933, Paul and Trask 1933, Trask *et al.* 1937, Burnet and Keogh 1938, Kessel *et al.* 1939, Stimpert and Kessel 1939).

Immunity.—In man second attacks of poliomyelitis are rare, but they do occur. Monkeys can often be re-infected successfully, with either the homologous or a heterologous strain (Flexner 1937). Active immunization of monkeys against intracerebral inoculation is possible by repeated intracutaneous inoculation with

living virus, but complete protection is not easy to obtain (Aycock and Kagan 1927, Stewart and Rhoads 1929). The serum of convalescent patients and monkeys, and of actively immunized monkeys, frequently but not always, contains substances capable of inactivating the virus *in vitro*. Observations have shown that neutralizing bodies are often present in the serum of persons who have never suffered from the clinical disease or been in known contact with infection. The test for these bodies is usually made by mixing the serum with a virus suspension, incubating at 37° C. for 2 hours and keeping in the ice-chest overnight, and injecting the mixture intracerebrally into *rhesus* monkeys (Aycock and Kramer 1930). Excluding new-born infants, whose blood often contains temporary antibodies, it is found that neutralizing bodies in the serum increase in frequency with age. In urban districts approximately 75 per cent. of children contain them by the age of 15 years. Most workers have concluded that these bodies represent specific antibodies resulting from latent infection and immunization. This view necessitates the belief that poliomyelitis infection is much more widespread than has hitherto been believed. The difficulty of accepting such a conclusion has led various workers, notably Jungeblut and his colleagues (Jungeblut 1933, Jungeblut and Engle 1933, 1934), to suppose that these antibodies are developed as part of the normal physiological maturation of the individual and do not necessarily denote previous exposure to infection. More assumptions appear to be entailed in this view than in supposing that active immunization is responsible. We do not wish, however, to discuss this question here, since reference has already been made to it in Chapter 49. Until we are in a better position to interpret the significance of the presence of neutralizing bodies in the serum, we shall be wise to refrain from drawing too far-reaching conclusions on the epidemiology of the disease.

It may be mentioned that there are no satisfactory serological or skin tests to help in the *diagnosis* of the disease. Cell changes in the cerebrospinal fluid are often detectable, but the virus itself can never be demonstrated in the fluid.

Prophylaxis, Vaccination and Serum Treatment.—If our views on the frequency of latent infection are correct, it is clear that the detection and removal of carriers are as little likely to be successful in preventing poliomyelitis as they are in preventing cerebrospinal meningitis. There is, however, evidence to suggest that infection is restricted mainly to cases and close contacts, so that control measures over such persons may be worth taking (Pearson and Rendtorff 1945, Pearson *et al.* 1945). General protective measures must follow those common to all droplet-borne respiratory infections. During an outbreak overcrowding should be avoided, ventilation should be increased, and children should spend as much time in the open air as possible. Operations on the nose and throat should be postponed, unless urgent. Cases and close contacts should be segregated for at least 3 weeks. Children in an infected house should be kept away from school for the same length of time. The advantage of closing residential schools is doubtful; and the balance of opinion is against it.

Great hopes were raised by the work of Armstrong and Harrison (1935, 1936) on the *chemoprophylaxis* of the disease. These workers brought evidence to suggest that the application to the nasal mucosa of a 2–4 per cent. solution of alum, or better of a 0·32–0·64 per cent. solution of picric acid, was capable of increasing the local resistance of monkeys to intranasal infection with the virus. Schultz and Gebhardt (1937) found that a 0·5 per cent. solution of zinc sulphate was even more effective. Field trials, however, on human beings in the United States and Canada have been disappointing (see Armstrong 1937,

Tisdall *et al.* 1937, Schultz and Gebhardt 1942). Not only have these agents no apparent prophylactic effect, but they may do considerable local damage by causing extensive coagulation necrosis of the olfactory epithelium. Moreover, since there is serious doubt as to whether infection in man occurs by the nose, the rationale of this form of prophylaxis rests on very slender grounds. The method has now been generally abandoned.

Attempts to *vaccinate* monkeys, and later children, against the disease have been numerous of late years, though it seems clear that mass immunization would be practicable only under quite exceptional conditions. Kolmer and his colleagues (Kolmer and Rule 1934*a*, *b*, Kolmer 1935, Kolmer *et al.* 1935) have used a 4 per cent. suspension of infected monkey cord in 1 per cent. sodium ricinoleate. The virus, though living, is said to be attenuated. Brodie (1934*b*) and Brodie and Park (1935), on the other hand, recommend a vaccine in which the virus has been inactivated by exposure to 0·1 per cent. formol at 37° C. for 8–12 hours. Both of these vaccines have been tried on a small scale in the United States. The demonstration, however, by Olitsky and Cox (1936) that Kolmer's vaccine may occasionally give rise to poliomyelitis in monkeys, and the even more serious development of poliomyelitis in children, occurring apparently as the result of prophylactic vaccination (Leake 1935), have led to the discontinuance of these vaccines.

As has already been pointed out, the blood *serum* of convalescent human patients often contains immune bodies capable of neutralizing the virus. During an epidemic, serum from such convalescent patients may be injected prophylactically into young children who have been exposed to infection, in a dose of 10 ml. subcutaneously, the injection being repeated in a month if the epidemic persists. Serum from human convalescents may likewise be used for treatment. According to Aycock and Luther (1928), it should be given in the pre-paralytic stage of the disease. By giving intravenous and intraspinal injections of serum during this stage, they obtained evidence that the incidence and severity of the subsequent paralysis was decreased in comparison with untreated patients (Aycock *et al.* 1929). Further experience, however, of serum treatment, even in the pre-paralytic stage of the disease, has yielded disappointing results. Park (1932) collected figures referring to the treatment of 439 patients in the pre-paralytic stage of the disease with serum. The serum was given subcutaneously, intramuscularly, intravenously, intraspinally, or by two or more of these routes in combination. The total dosage amounted to 25–100 ml. The results, which are given in Table 190, failed to

TABLE 190

SHOWING THE CONDITION OF TREATED AND UNTREATED CASES OF POLIOMYELITIS AT THE END OF THREE WEEKS (After Park 1932).

	No. of Cases.	Died. Per cent.	Paralysis. Per cent.	Weakness. Per cent.	No Paralysis or Weakness. Per cent.
Treated	519	3·8	19·6	7·7	68·8
Controls	408	0·9	11·0	14·2	73·7

show any advantage, as regards the development of paralysis, of the serum-treated over the control patients. Somewhat similar results are recorded by Fischer (1934), who compared 477 serum-treated patients in the pre-paralytic stage with 102 controls. Both as regards case mortality and the degree of paralysis the control group showed some slight, though probably insignificant, advantage over

the serum-treated patients (see also Schultz and Gebhardt 1935, Jensen 1935, Eagles *et al.* 1937, Aycock 1941).

On general grounds it seems very improbable that serum would exercise any beneficial effect. The virus is never found in the blood, and circulating antibodies are incapable of reaching it in its intraneural situation (see Perdrau 1938, Faber 1941). Mixed *in vitro* with the virus, neutralizing antibodies are effective, but not if injected separately into the infected animal (Armstrong 1941). These considerations are supported by Burnet's (1940) finding that the neutralizing antibody level may be unaffected by passage of a patient through a clinical attack of the disease, and that persons who develop the disease often have relatively large amounts of circulating antibody at the time of their illness; and by Howe and Bodian's (1945) observation that the administration of homologous hyperimmune serum to chimpanzees before alimentary infection has apparently no effect, as judged by comparison with control animals, on the development or severity of the disease. The apparently beneficial effect of serum that has occasionally been reported in field trials would appear to be due in large part, if not wholly, to the inclusion in the treated group of mild, non-paralytic cases that are not ordinarily reported.

Infectious Paralysis of Guinea-pigs

This disease occurs sporadically in guinea-pigs, and closely resembles poliomyelitis. According to Römer (1911), who first described it, it can be transmitted to normal guinea-pigs by the intracerebral inoculation of filtered or unfiltered brain or cord suspensions. After an incubation period of 9 to 22 days, the animals become febrile and lose weight; nervous disturbances develop, consisting of a gradually increasing muscular weakness, particularly of the hinder parts of the body; paralysis of the hind legs develops, and occasionally of the bladder. The disease lasts from 3 days to 3 weeks. Pathologically, the lesions are those of a disseminated meningo-myeloencephalitis. They differ from those of poliomyelitis in showing greater meningeal infiltration, and in being most severe around the central canal of the cord. The virus is constantly present in the central nervous system; it is also found in the prevertebral, inguinal, and mesenteric lymph glands, and occasionally in the liver and spleen.

BENIGN LYMPHOCYTIC CHORIOMENINGITIS. PSEUDO-LYMPHOCYTIC CHORIOMENINGITIS. SWINEHERDS' DISEASE

These three diseases may be considered together. In 1925 Wallgren coined the term " acute aseptic meningitis " to comprise cases of an acute febrile disease, accompanied by meningeal irritation and sometimes by inflammation of the upper respiratory tract, terminating favourably within 10–14 days. Since then, three different viruses capable of giving rise to a benign aseptic meningitis have been described: (1) the virus of benign lymphocytic choriomeningitis, which has been found mainly in the United States; (2) the virus of pseudo-lymphocytic choriomeningitis, which has been isolated on only two occasions—both in this country; and (3) the virus of swineherds' disease, which, so far, appears to be confined to France, Switzerland and Italy. These three viruses account for about one-third

of the cases of acute aseptic meningitis; the ætiology of the remainder is unknown (Report 1942).

Benign Lymphocytic Choriomeningitis.

Armstrong and Lillie (1934), while investigating a fatal case of St. Louis encephalitis, isolated a virus, quite different from the ordinary St. Louis virus, which gave rise in experimentally inoculated monkeys and mice to a lymphocytic choriomeningitis. An apparently identical virus was isolated by Scott and Rivers (1936) (see also Rivers and Scott 1936) from two benign cases of non-bacterial lymphocytic meningitis in adult males in the United States, and by Findlay, Alcock, and Stern (1936) in this country from the cerebrospinal fluid of two patients who exhibited vague nervous symptoms following a febrile attack. A similar or identical virus was isolated by Findlay and his colleagues from an irradiated mouse showing nervous phenomena. Traub (1936*a*, *b*, 1938, 1939) established the existence of an endemic infection with the same virus in a colony of normal mice, and showed that infection occurred either *in utero* or shortly after birth.

In man, the disease is uncommon during the first decade. Males and females are equally affected. Most cases occur in the winter and spring (see Blackfan 1941). The incidence is not known, but judged by the finding of neutralizing antibodies in the blood serum of patients who have recovered from catarrhal infections of the upper respiratory tract without meningeal symptoms, and of apparently normal persons, the infection would appear, in the United States at least, to be fairly widespread (see Armstrong and Wooley 1937, Wooley *et al.* 1939). A history of an influenza-like attack, followed in ten days or so by meningeal symptoms, is suggestive of the disease. Though the virus has been demonstrated once in the human nasopharynx by MacCallum and Findlay (1939), it is by no means certain that infection is spread by droplets. On the whole, the evidence suggests that man becomes infected from grey mice (*Mus musculus*), which are known to excrete the virus in the urine, faeces, semen, and nasal secretions (see Traum 1936*b*, Armstrong and Sweet 1939, Armstrong *et al.* 1940). A few laboratory infections have been reported.

The disease can be transmitted to mice, guinea-pigs, monkeys, and human beings.

Five to twelve days after intracerebral inoculation *mice* become ill, develop tremors of the limbs, and die in 1–2 days with spastic convulsions of the hind legs. Inoculated subcutaneously or intraperitoneally they develop an inapparent infection followed by immunity (Ronse 1937). *Guinea-pigs* develop a febrile reaction after intracerebral, intranasal, or subcutaneous inoculation, lose weight, and often die, though not before the 12th day. Meningitis is uncommon, but pneumonia may occur. The spleen and suprarenal glands are said to be most heavily infected, the liver and lungs less so (Mendoza 1937). According to Shwartzman (1944) the virus, in mice and guinea-pigs, is said to be associated with the red blood corpuscles. In *monkeys*, the virus has been shown to be widely disseminated throughout the tissues; pathologically, areas of lymphocytic infiltration are found in most of the organs (Armstrong *et al.* 1936, Lillie 1936). Not all strains are pathogenic for guinea-pigs. The same applies to rats. Rabbits and pigs are insusceptible. Lépine, Mollaret and Kreis (1937) have described the effect of inoculating *human beings*. The subcutaneous injection of 2 ml. of virulent mouse brain was followed in 36–72 hours by a benign and almost symptomless fever of an undulating type lasting up to 3 weeks. Two or three waves occurred, separated by apyrexial intervals. In about half the patients the last wave of the fever was accompanied by a meningeal reaction, starting abruptly and characterized by headache, sometimes vomiting, and by

contractures with a positive Kernig sign. The symptoms began to disappear in 2–3 days.

The virus seems to be about 37–60 mμ in diameter (Scott and Elford 1939). It has been cultivated successfully on the chorio-allantoic membrane of the developing chick embryo (Bengtson and Wooley 1936), and in a simple minced chick embryo serum medium (MacCallum and Findlay 1940). In 50 per cent. neutral glycerol phosphate solution at 0° C. it may remain alive for a few months, and also when dried *in vacuo* and kept at 0° C. in sealed ampoules, but it dies rapidly under other conditions. A suspension kept at 20° C. was found to be non-infective within 3 hours (Lépine, Sautter and Kreis 1937). A relatively heat-stable soluble antigen of protein nature can be demonstrated in the virus by precipitin and complement-fixation reactions (Smadel *et al.* 1939, 1940). It appears to be different from the antigen that reacts with neutralizing antibodies in immune serum.

Diagnosis.—The cerebrospinal fluid does not clot; the sugar and chlorides remain normal; and the fluid contains a considerable excess of lymphocytes. The virus may be demonstrated in the blood, or in the cerebrospinal fluid soon after the onset of meningeal symptoms, by inoculation intracerebrally into mice derived from a known non-infected stock, and its identity may be determined by neutralization with specific sera or by a specific complement-fixation reaction (Smadel and Wall 1941). Indirectly, the diagnosis may be assisted by the demonstration of complement-fixing antibodies (see Casals and Palacios 1941) or of neutralizing antibodies (Armstrong and Wooley 1935, Wooley *et al.* 1937) in the patient's serum. Antibodies appear to be somewhat variable in their appearance, and there is some evidence to suggest that complement-fixing antibodies appear rather earlier than neutralizing antibodies.

Pseudo-lymphocytic Choriomeningitis.—Only two cases of this disease have so far been described. Clinically, they resembled benign lymphocytic choriomeningitis. MacCallum and his colleagues (1939) isolated a virus from the cerebrospinal fluid of each of the patients. It was considerably larger in size—150 to 225 mμ—than the true choriomeningitis virus. It gave rise in mice, guinea-pigs, and *rhesus* monkeys to a clinical and pathological picture very similar to that of choriomeningitis, except that in mice inoculated intracerebrally the incubation period was shorter—4 to 5 days instead of 5 to 12 days—and the pathological lesions were less extensive. Judged by cross-immunity tests in mice, the two viruses appeared to be distinct.

Swineherds' Disease.—A disease affecting swineherds and occurring in Haute-Savoie, Switzerland, and Italy, was described in 1914 by Henri Bouchet under the name of pseudo-typhoid-meningitis. From the observations of Durand and his colleagues (1936, 1937, 1938) and of Campanacci (1939) there seems little doubt that the disease is due to a filtrable virus, and that infection occurs from pigs to man—possibly by the rubbing of infected fæces into the skin. After an incubation period given variously as 2–4 weeks and 5–8 weeks, the disease begins with fever, headache, and severe muscular pains. Digestive troubles appear—foul breath, green vomit, abundant fœtid diarrhœa, meteorism, and sometimes rectal hæmorrhage. After about four days of this preliminary typhoid state, the temperature falls to normal, but in two days or so it rises again and meningeal symptoms appear. The cerebrospinal fluid is under considerable pressure and the lymphocytes usually number several hundred per c.mm. After a further three or four

days the meningeal phase comes to an end and the fever falls by crisis or lysis. Conjunctivitis and a maculo-papular rash may be seen in some cases. The disease is practically never fatal, and leaves behind it a fairly solid immunity. The blood is infective during the first week, and the urine during the second week and early stage of convalescence. The infectivity of the cerebrospinal fluid is variable. The virus, which passes through an L2 candle, can be transmitted to swine, cats, ferrets, rats, mice, and guinea-pigs. Experimental inoculation of man is followed, after an incubation period of about 12 days, by a disease similar to, but on the whole milder than, the natural disease. In *pigs*, the natural disease is characterized by fever, digestive disturbances, salivation, stiffness of the neck, muscular spasms, circular movements, and often terror of food. The case mortality is very low. At post mortem punctiform hæmorrhages are found in the intestine, renal pelvis, brain and throat. The disease may occur in epidemic form. Young pigs, 1–2 months of age, are chiefly affected.

RABIES

Rabies is a disease of animals affecting particularly dogs, cats and carnivorous wild animals; herbivora are less frequently attacked. The disease is transmissible to human beings by the bites of rabid animals, notably dogs, cats, wolves, and jackals. The incubation period varies according to the age of the animal, the situation of the bite, and the severity and nature of the bite. Generally speaking, it varies in animals from 2 to 8 weeks, and in human beings from 6 to 8 weeks; it tends to be shorter in young animals and children, and after severe lacerated or deep punctured wounds about the head, face or neck. The disease does not uniformly appear after infection; according to Hutyra and Marek (1926), only 30–40 per cent. of dogs bitten by rabid animals develop the disease. In human beings the proportion of persons bitten by rabid dogs who die of rabies or contract the disease is given by Cornwall (1923) as 35 per cent. and by Hull (1941) as 16 per cent. The reasons for this are not clear; it seems probable, however, that the body is able to withstand small doses of the virus, especially if the virus does not come into intimate contact with exposed nerves. Once the disease has developed, it is almost always fatal.

Sometimes the rabies virus gives rise in human beings to an acute *ascending myelitis*. The first case of this type was recorded by Knutti (1929), who based his diagnosis on the presence of Negri bodies in the ganglion cells of the spinal cord, and on the development of rabies in inoculated rabbits. A very remarkable outbreak of the disease was observed by Hurst and Pawan (1931) in Trinidad. Besides the occurrence of ascending myelitis in human beings, a form of paralytic rabies, erroneously diagnosed as botulism, was also met with in cattle. Investigation failed to disclose any history of a bite by a rabid animal, but evidence was brought to show that both the human and the cattle disease was due to vampire bats which conveyed the disease by sucking the blood of their victims (see also Pawan 1936). Further observations show that paralytic rabies is apparently widespread among animals in Brazil, where infection is carried by the vampire bat *Desmodus rufus* (de Verteuil and Urich 1936). On cattle ranches the disease may reach epidemic proportions (Molina 1938). In South Africa the dog appears to play a negligible rôle in the perpetuation of infection. The main carriers are wild carnivora of

the mongoose family, particularly the meercat *Cynictis penicillata* (see Snyman 1940).

Animal Inoculation.—Rabies is transmissible to animals by subdural, intracerebral, or intravenous inoculation ; subcutaneous and cutaneous inoculations are less regular in their results. Pasteur and his colleagues (1881) found that dogs, when inoculated into the subarachnoid space over the brain with a suspension of the brain of a rabid dog, developed rabies after an incubation period of 1 to 2 weeks, and died within 3 weeks. If the virus is inoculated subdurally into a rabbit, the incubation period of the disease is about a fortnight ; but if the virus is passed in succession through a series of rabbits, the incubation period gradually falls, till after 20 to 25 passages it is only 8 days, and after a further 20 to 25 passages it is only 7 days (Pasteur 1885). The effect of passage is to convert the original " street virus " into a " fixed virus." These two viruses differ in certain respects. Thus, according to Levaditi, Nicolau and Schoen (1924), the fixed virus has a greater affinity for the nervous system of the rabbit than the street virus ; allied with this increased neurotropism, is the failure of the fixed virus to give rise to Negri corpuscles. Inoculated on to the scarified skin of the rabbit, both viruses give rise to rabies ; but if they are injected subcutaneously, the street virus alone proves virulent. It would appear that by passage through the rabbit's brain, the fixed virus has acquired a strong neurotropic affinity, which enables it to give rise to rabies in 7 days after subdural injection, but which usually renders it avirulent on subcutaneous inoculation. The street virus, on the other hand, takes about 14 days to produce rabies on subdural inoculation, and usually proves virulent when introduced subcutaneously. Fixed viruses can likewise be produced by passage through guinea-pigs, dogs, hens, and monkeys (Pasteur *et al.* 1884). Both street viruses, and the fixed viruses derived from them, show considerable variability in their virulence for animals ; some rarely produce infection when inoculated subcutaneously, others always do so (Marie *et al.* 1927). Pasteur (Pasteur *et al.* 1884) found that by passage through the brain of monkeys, the virus diminished in virulence for dogs, though when passed through rabbits or guinea-pigs it uniformly increased in virulence.

The virus is present in the saliva of rabid animals, and has sometimes been demonstrated in it 4 days before the onset of clinical symptoms. It is also found in the central nervous system, the peripheral nerves, and in the salivary glands, less regularly in the cerebrospinal fluid. Occasionally it may be demonstrated in the blood and the internal organs (Pasteur *et al.* 1884, Remlinger and Bailly 1931, 1932). The virus passes along the nerves from the local injury, and reaches the central nervous system ; this is shown by the fact that (1) the animal may live after resection of experimentally infected nerves ; (2) the resected nerves are themselves infective ; (3) the portion of the spinal cord in connection with the infected nerve becomes infective before other parts of the central nervous system (di Vestea and Zagari 1889, Marie *et al.* 1927). According to Nicolau and Galloway (1928), the virus, when introduced into the brain, may spread centrifugally, and be found in such nerves as the brachial and sciatic ; the passage of the virus along the nerves sets up an interstitial neuritis. It has been suggested that the salivary glands owe their infectivity to the presence in them of neurones, which may occur as single cells or as ganglionic aggregations, and which are situated just under the epithelium ; if the epithelium is abraded, the virus is set free from the neurones, and infects the saliva (Manouélian and Viala 1927, 1928, for references see McKendrick 1928*b*).

Properties of the Virus.—The rabies virus can pass through Berkefeld candles. Galloway and Elford (1936), from filtration experiments carried out with gradocol membranes on a strain of fixed virus, estimate its size as 100–150 mμ. This agrees with the value obtained for another strain of fixed virus by Yaoi, Kanazawa and Sato (1936). The virus can be grown in tissue cultures containing embryo brain and human or monkey serum (Kanazawa 1936, Webster and Clow 1937). It can also be cultivated on the chorio-allantoic membrane of the developing chick embryo, provided 5 or 6-day embryos are used (Kligler and Bernkopf 1941). Cultivated strains tend to lose their virulence fairly rapidly. According to Sankaran, Iyengar and Beer (1934), the virus can be separated from infected rabbit

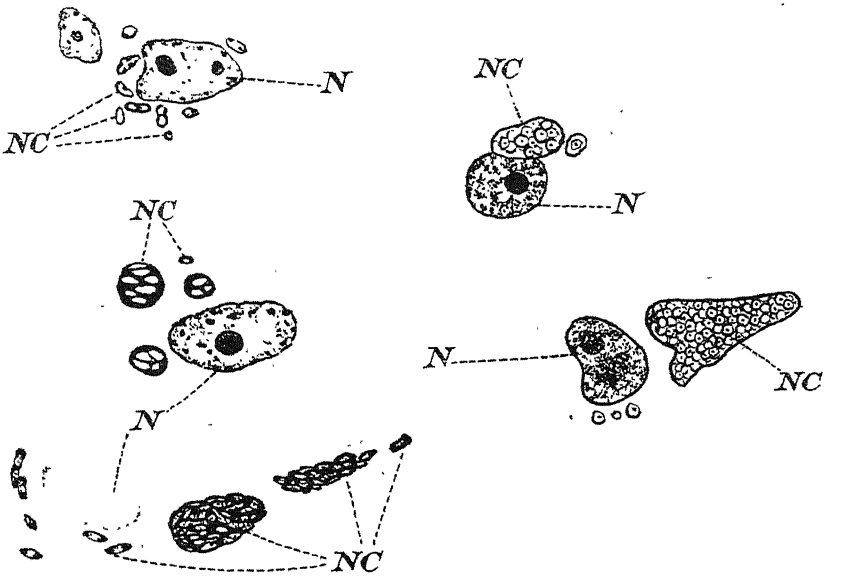

FIG. 302.

Negri corpuscles in Ammon's horn. N = nucleus. N.C. = Negri's corpuscle. (After Manouélian, and Manouélian and Viala.)

brain by electrophoresis. It is not very resistant. It is destroyed by exposure to a temperature of 60° C. for 30 minutes. Slow drying gradually renders it inert, but if rapidly dried it may retain its infectivity for months. The fixed virus is very sensitive to the photodynamic action of methylene blue (Shortt and Brooks 1934, Galloway 1934) and to irradiation with ultra-violet light (Sankaran and Beer 1935). It is readily killed by bile. Little is known about its antigenic structure, but most strains seem to resemble each other fairly closely (Remlinger and Bailly 1930, Havens and Mayfield 1933).

One of the characteristic properties of the street virus is its power of giving rise to inclusion bodies in the nerve cells, known as Negri corpuscles (Negri 1903*a*, *b*) (Fig. 302). They are found most frequently in the cytoplasm and dendritic prolongations of the nerve cells, particularly in those of Ammon's horn. Usually they

are about 3–10 μ in diameter, but they vary from 1 to 27 μ (Manouélian 1912). They generally conform in shape to their situation in the nerve cell, being rounded when in the cytoplasm, oval when compressed by the nucleus, and fusiform when in the dendrons. Each Negri body consists of a homogeneous mass containing clearer corpuscles, which may themselves contain one or more corpuscles, and sometimes short rods or granules. When stained by Giemsa, the homogeneous ground substance is lightish blue; the larger corpuscles are pink, and the small corpuscles, rods, or granules are red or reddish-violet in colour. Fine blue-staining granules, which Negri regarded as forming a diffuse nucleus, are scattered throughout the body. In infections with fixed virus, Negri bodies are not usually present, but instead very fine granules, staining red with Mann's method, may be found in enormous numbers in the nerve cells (Manouélian 1912). The Negri bodies vary considerably in appearance. There is little doubt that they represent intracellular micro-colonies of the virus. Their presence in nervous tissue is diagnostic of infection, and their demonstration either directly, or indirectly by the mouse passage method (Webster and Dawson 1935), affords the most rapid means of determining the presence of infection in a suspected animal.

Diagnosis.—In attempting to reach a diagnosis of rabies in a human being before the disease has declared itself, it is important if possible, not to kill the animal responsible for the bite, but to keep it in safe captivity for a few days to see whether the typical symptoms of the disease develop. If it is killed before the onset of the paralytic stage, no Negri bodies may be found in the brain. Once the animal is paralysed, it should be killed, and the brain examined by a rapid section method for Negri corpuscles. If the animal has been prematurely destroyed, or if the brain has been improperly preserved, resort should be had to the mouse inoculation test described by Webster and Dawson (1935).

Webster (1936) recommends that sterile pieces of Ammon's horn of the suspected animal should be made into a 5 or 10 per cent. suspension with distilled water, and that 0·03 ml. should be inoculated intracerebrally and 0·25 ml. intramuscularly into each of 6 mice belonging to the specially susceptible Swiss breed. One animal should be sacrificed on the 5th, 6th, and 7th days respectively, and its brain examined for Negri bodies. The remaining three are observed for 4 weeks for signs of rabies. In practice, a negative diagnosis may usually be given in 3 weeks (Thomas 1939). The advantage of the mouse over the rabbit is that it is more susceptible, it is easier to inoculate intracerebrally, and it develops rabies, on the average, a week earlier.

If the brain of a suspected animal cannot be examined fresh, it should be packed in ice before transmission to the laboratory; or, alternatively, half of it may be sent in 10 per cent. formalin for section and half in 50 per cent. glycerol for inoculation. It is possible that the complement-fixation test may be found of value in diagnosis (Casals and Palacios 1941), but so far little work has been carried out on it.

Prophylactic Treatment of Rabies.

After infliction of the bite, an attempt should be made to destroy as much of the virus in the wound as possible. For this purpose, treatment with a 20 per cent. solution of soft soap is said to be as effective as cauterization with fuming nitric acid (Shaugnessy and Zichis 1943). Tincture of iodine is also useful, if applied within 30 minutes.

Rabies is a fatal disease, and once symptoms have declared themselves, treat-

ment is of no avail. But the disease is characterized by a long incubation period ; and it was Pasteur (1885) who realized the possibility of utilizing this period for carrying out specific vaccine treatment. Pasteur found that the spinal cords of rabbits dying of experimental rabies gradually lost their virulence when dried in air over KOH. By inoculating dogs with cords dried for varying periods, beginning with the least virulent and working up to the most virulent, he was able to immunize them to both natural and experimental rabies. His first human patient was a boy, Joseph Meister, aged 9 years, who had been bitten by a rabid dog in 14 places. Treatment was commenced 60 hours after the bite. Subcutaneous inoculation was performed, starting with a cord that had been dried for 14 days, and working up to a cord only 1 day old ; altogether 13 injections were given within 11 days. Rabbits inoculated with the cords 7 to 14 days old remained well ; rabbits inoculated with the cords 1 to 6 days old died after an incubation period increasing from 7 to 14 days. The cords first injected were therefore avirulent ; those used for the later injections were virulent. The treatment was a complete success, and formed the starting point of a system of preventive inoculation that is of world-wide distribution.

Pasteur's original method of inoculation is still used to-day, but a number of other methods have been developed by different workers. The most important of these are : (1) Högyes' method ; this consists of the subcutaneous injection of 1/100 to 1/10,000 dilutions of a 1 per cent. suspension of fixed virus of full virulence. This method has been used extensively with good results ; occasionally, however, the fixed virus may cause infection. (2) Babes' method ; in this the spinal cord is heated to 80°, 60°or 45° C. for 10 minutes, in order to attenuate the virus to varying degrees. (3) Semple's method ; the virus is killed with 1 per cent. carbolic acid. (4) Alivisatos' (1922, 1926) method ; the virus is attenuated with ether. (5) Fermi's method of sero-vaccination. Fermi (1926) prepares his vaccine by exposing a 5 per cent. suspension of fixed living virus to 1 per cent. phenol for 1 to 10 days. The serum is prepared by the immunization of horses with the vaccine. The vaccine and the serum are mixed in varying proportions, and injected twice daily.

It is very difficult to ascertain which of these methods is of most value. McKendrick (1940), who has reviewed the results furnished over a number of years by the Pasteur Institutes in different countries, comprising a total of over one million persons treated, finds that there is very little to choose between them. From a careful analysis of the figures he regards it as improbable that any of the vaccines differs in efficacy from the rest by more than 25 per cent. On the other hand, paralyses resulting from the vaccine itself were observed about three times as often in patients treated by Pasteur's original method or by Högyes' dilution method as in those receiving vaccines killed by phenol, ether, or heat. Paralyses of this type constitute one of the objections to the treatment. They occur about once in every 3,000 to 10,000 patients, according to the type of vaccine used. The commonest time for them to appear is between the 11th and 30th days after the bite, that is to say, considerably before the onset of rabies in untreated persons. They prove fatal in about 25 per cent. of cases. What they are due to is not yet known ; for a discussion of the subject see Remlinger (1927).

The average case mortality in treated patients in McKendrick's series varied over a series of years between 0·23 and 0·49 per cent.

How, it may be asked, can a dead vaccine, inoculated into the patient after living virulent virus has gained access to the body, afford any protection against

the disease? The answer to this question is still being sought. The virus is known to be neurotropic, and almost certainly finds its way to the brain and cord by way of the nerves. If an attenuated virus was inoculated in enormous quantities very soon after the bite, it is conceivable that some of it might reach the susceptible nerve cells and block the entry of the virulent virus. But how can this happen with a dead vaccine, unless transport along the neurones is purely mechanical? Yet, from McKendrick's figures a dead vaccine appears to be just as efficacious as a living attenuated virus. Moreover, there seems to be no advantage in early treatment; the mortality of those treated 0–4, 5–7, or 8–14 days after the bite was, among Europeans, 0·19, 0·10, and 0·06 per cent. respectively. Animal experiments do not increase our confidence in vaccination. The observations of Shortt and of Covell and their colleagues in India (Shortt *et al.* 1934, 1935, Covell *et al.* 1936), and of other workers (see Webster 1939*b*) seem to show that (1) no vaccine can protect an animal *after* exposure to infection by rabies virus, (2) vaccine given *before* exposure to infection is effective only provided (*a*) it is given repeatedly and in large doses, totalling at least 1 per cent. of the body weight, and (*b*) the test dose is given subcutaneously, intramuscularly, or by some other route than the intracerebral.

Considerations such as these have led many workers to question the value of the vaccine treatment of rabies. Ever since Pasteur recorded his apparently brilliant successes, persons who have been bitten by rabid animals have been given treatment as a matter of course. In such a disease it would be unjustifiable to withhold it so long as there was any reason to believe that it might confer some degree of protection. The result has been that there are no adequate control figures available. A high proportion of persons treated have probably not been bitten by rabid animals, and, of those who have, probably not more than a quarter would have developed rabies anyway. The figures of the Pasteur Institutes therefore throw little light on the main question at issue.

Progress in the past has been hampered by the failure of a satisfactory technique for standardizing anti-rabic vaccines. The mouse inoculation test, however, introduced by Webster (1939*a*) promises to be of value for this purpose. By its use Webster found that commercial vaccines of the killed type were often devoid of protective action or were effective only in doses greater than those recommended by the manufacturers (see also Wyckoff and Beck 1940, Habel 1940*a*). Habel (1940*b*), moreover, has noted considerable variations in the antigenic potency of the different strains used to prepare commercial vaccines. In an effort to produce a more reliable product, Webster and Casals (1942*a*, *b*) have prepared a vaccine from infected dog brain rendered non-virulent by exposure to ultra-violet light. In the laboratory favourable results were obtained in the protection of mice and dogs, but its use on a field scale under properly controlled conditions will have to be awaited before an opinion on its value can be expressed.

The Paris Conference on rabies recommended that prophylactic treatment should be applied to all human patients whenever they had been bitten, or whenever a mucosa had been contaminated with rabid saliva, even though no wound had been inflicted. The treatment should be commenced as soon as possible after the bite. In countries where rabies is common, they recommend that all dogs should be vaccinated with a single dose of killed or of fixed virus, and revaccinated every year. But a dog or other animal that has been bitten by a certainly rabid animal must be killed, whether vaccinated or not; if bitten by a suspect animal, then

the dog may be vaccinated therapeutically, and kept in quarantine for 6 months. The measures they recommend for the elimination of rabies consist in restricting all dogs not fitted with muzzles to the homes of their owners, and in destroying all stray dogs. In this country, where the muzzling orders and the strict supervision of all imported dogs have been carried out when need has arisen, rabies is non-existent.

How far prophylactic inoculation of dogs is effective in practice, it is impossible to say. Gautier (1940–41), who reviewed the evidence, was able to reach no definite conclusion. Webster (1939*b*) found that a single dose of the usual canine vaccines was ineffective, thus confirming the previous observations of Barnes and his colleagues (1930, 1934). Whether the ultra-violet irradiated vaccine of Webster and Casals (1942*a*, *b*) will prove more efficacious, it is as yet too early to say. For much useful information on rabies, the reader is referred to the monograph by Remlinger and Bailly (1938*a*).

Pseudorabies

Synonyms: Mad itch: Infectious bulbar paralysis: Aujeszky's disease.

This disease, which was described by Aujeszky in 1902, has only recently attracted much attention. It appears to be an acute infection of the central nervous system affecting dogs, cats, cattle, horses, pigs, goats, sheep, rats, and mice, but not man. Though originally met with in Hungary, it has now been reported from a number of other European countries and from both North and South America. Unlike rabies the incubation period is very short—only a matter of hours—the onset is brusque, there is intense pruritus, which often completely dominates the clinical picture, the mental faculties are preserved, paralysis occurs very late and does not involve the lower jaw, the disease lasts only 24–48 hours, and sudden death is common (Remlinger and Bailly 1934). Except in pigs, the case-mortality rate is usually very high. The mode of infection is still in doubt. According to Shope (1935), the disease in cattle is very fatal but non-contagious, whereas in pigs it is relatively mild but highly contagious. Shope believes that in pigs infection occurs by the nose, and that the abraded skin of cattle can probably be infected from contact with the pig's snout. A study of neutralizing bodies in the serum suggests that pseudorabies is a highly prevalent but unrecognized disease in the hogs of the Middle West. There is some evidence that the disease is spread by rats, and that pigs may become infected by feeding on contaminated material.

The disease can be reproduced experimentally in most animals, though monkeys appear to be fairly resistant. In the rabbit, which is the most susceptible of the small laboratory animals, the disease exhibits a diverse and striking symptomatology. Infection is possible by practically any route. Intracerebral inoculation gives rise in 20–40 hours to a condition of wild excitement, accompanied by salivation, grinding of the teeth, blindness, and later coma and death. In rabbits injected subcutaneously the incubation period is 50–75 hours; the animals then start scratching and biting the site of inoculation; their efforts become increasingly savage till the skin is hairless, abraded, and bleeding; feebleness sets in, and death occurs in a state of collapse 6–24 hours after the onset of pruritus (Shope 1931). The clinical picture, however, is very variable, and may assume an encephalitic, pseudo-herpetic, meningeal, paralytic, pruriginous, fulminating, or even abortive form (Remlinger and Bailly 1934). Some animals can be infected by feeding.

The causative virus is widely distributed in the body, being often demonstrable in the blood and internal organs as well as in the central nervous system. It may be present in the saliva, but there is no evidence to suggest that the disease is transmitted by biting (Remlinger and Bailly 1937). In some animals it is said to be excreted by the urine. It can pass through a Berkefeld W filter, and has been found by the gradocol membrane technique to have a particle size of 100–150 mμ (Elford and Galloway 1936). It is killed by exposure to a temperature of 55°–60° C. in 35 minutes, but survives in 50 per cent. glycerol in the ice-chest for many months (see McKinley 1929). It is readily destroyed by bile. It has been successfully grown in tissue cultures containing rabbit or guinea-pig testicle and in a minced chick embryo medium (Traub 1933). It can also be cultivated on the chorio-allantoic membrane of the chick embryo (Mesrobeanu 1938); focal lesions are produced, and the embryo dies in 3–4 days (Glover 1939); the virus invades the central nervous system of the embryo (Bang 1912). Cross-immunity tests show that it is distinct from the virus of rabies (Gerlach and Schweinburg 1935), and from the herpes virus (Nicolau *et al.* 1937), which in many ways it resembles (see King 1940). Immune sera that neutralize the virus can be prepared by inoculation of guinea-pigs (Shope 1931). Antigenically, only one type of virus has so far been recognized (Remlinger and Bailly 1937).

Histologically, the picture varies in different animals. In general, gross lesions are few. Hyperæmia of the meninges and small hæmorrhagic extravasations may be seen. In rabbits and guinea-pigs the virus gives rise to local inflammation and necrosis at the site of inoculation, passes up the peripheral nerves as evidenced by the presence of intranuclear inclusion bodies and causes degeneration of the nerve and glial cells in the spinal ganglia and segments of the cord corresponding to the peripheral nerve invaded (Hurst 1933). The lungs may show intense hæmorrhagic lesions, containing virus in considerable quantity (see Galloway 1938). In cows, primary degeneration of the nerve and glial cells occurs in the cerebral cortex, especially Ammon's horn.

Animals that recover from an attack of the disease possess a strong immunity even against intracerebral inoculation (Gerlach and Schweinburg 1936); but all attempts so far to immunize healthy animals by vaccination have proved a failure. For a general description of the disease and its causative virus the reader is referred to an article by Galloway (1938) and to the monograph by Remlinger and Bailly (1938*b*).

Scrapie

Synonym: French. *Tremblante du mouton*

Scrapie is a disease of sheep that occurs in Great Britain - mainly the northern part—and on the continent of Europe. The onset is often insidious and is characterized by undue excitability and jerky movements of the ears, eyelids, lips and limbs. Later, irritation of the skin occurs, starting at the root of the tail and gradually becoming generalized. Itching is intense and almost intolerable. Emaciation rapidly sets in, the animal becomes weaker and weaker, and dies in a fortnight or so. From start to finish the disease lasts 3 to 4 months. In the so-called "trotting" variety, the itching is less severe, but the animal periodically drops every now and again, as if dead, and then rises in a few minutes and resumes its trot. Pathologically, no characteristic lesions have been found. Early attempts

to transmit the disease by inoculation failed, possibly because the animals were not observed long enough. More recently, Cuillé and Chelle (1936, 1938) have shown that the brain and spinal cord are infective, and that the disease may be reproduced in susceptible sheep by subcutaneous, intra-ocular, epidural, or intracerebral inoculation. The incubation period, however, is very long; it is seldom less than a year and may extend nearly to 2 years. The infective agent appears to be filtrable, as a suspension of cord is still virulent after passage through a Chamberland L3 candle.

We append brief descriptions of two animal diseases whose position in our rough scheme of classification is very doubtful.

Salivary Gland Virus of Guinea-pigs

Cole and Kuttner (1926) observed greatly swollen epithelial cells in the salivary glands of guinea-pigs; they were found in 84 per cent. of full-grown animals. Injection of a suspension of the affected submaxillary glands intracerebrally into young guinea-pigs was followed by fever, cerebral irritation, and death in 5 to 7 days, with diffuse subacute meningitis. In the exudate large numbers of cells were found similar to those in the salivary glands. Similar cells were also seen in the lesions resulting from inoculation of the same suspension into the testicle, lung, tongue, and submaxillary glands of young guinea-pigs. Markham (1938) has recorded the occasional finding of characteristic inclusions in the epithelium of the convoluted tubules in the kidney of naturally infected animals. The virus is destroyed at 54° C. in 1 hour; it survives for 11 but not for 28 days in 50 per cent. glycerol. It passes through a Berkefeld N candle. The virus appears to give rise to no clinical symptoms in naturally infected guinea-pigs. Infected guinea-pigs are immune to the intracerebral inoculation of virus; in the serum of these animals neutralizing bodies can be demonstrated (Andrewes 1930). More recently Kuttner and Wang (1934) have described the presence of acidophilic intranuclear inclusion bodies in the submaxillary glands of hamsters, white mice, and wild rats; each of these animals appears to be infected by a specific virus. Similar inclusion bodies have also been noted in the salivary glands of human infants, but animal transmission experiments have proved unsuccessful.

Pappenheimer and Slanetz (1942) have described a generalized visceral disease of guinea-pigs characterized by intranuclear inclusions of the herpes type. Macroscopically, areas of greyish-white necrosis were found in the liver but, microscopically, lesions were present in the lungs, spleen, and kidney as well. Infection was not transmissible experimentally, and the relation of the disease to that caused by the salivary gland virus was not clear.

Periodic Ophthalmia of Horses

This disease is characterized by a recurrent serous uveitis, with an acute onset, subsidence in 4–10 days, and a remission after 3–6 weeks. The symptoms can be reproduced in horses by inoculation of a Berkefeld N filtrate of infective material into the vitreous humour. Rabbits are also susceptible (Woods and Chesney 1930).

CHAPTER 88

FILTRABLE VIRUS DISEASES—*Continued*

D. GROUP CHARACTÉRIZED BY CATARRHAL OR GENERALIZED INFECTION

MEASLES

MEASLES is a highly infectious disease of human beings, which is endemic throughout the world. In Europe and America epidemics tend to occur in alternate years, as a fresh susceptible population of children grows up. Among civilized peoples it is chiefly a disease of childhood, relatively mild in itself, but when complicated by respiratory infections—as it so often is—attended by a high mortality. Introduced, however, into non-endemic areas it affects young and old alike, and takes on a more malignant character. When it was imported, for example, into the Fiji islands in 1875, it carried off 20–25 per cent. of the entire population (see Brincker 1938). Most children exposed to infection for the first time contract the disease, but there is evidence that during epidemics a small proportion develop a latent infection resulting in a temporary or sometimes permanent immunity (see Halliday 1928, Stocks and Karn 1928, Enders 1941). In this country measles is a disease of winter and spring, the maximum mortality usually being recorded in April.

Anderson and Goldberger (1911) first recorded evidence indicating that measles could be experimentally transmitted to *monkeys*. The experiments of Nicolle and Conseil (1911, 1920) likewise suggested that monkeys were susceptible. The most convincing evidence, however, was brought by Blake and Trask (1921). These workers were able, by the intratracheal inoculation of filtered and unfiltered nasopharyngeal washings taken from measles patients 6 days before to 22 hours after the appearance of the rash, to produce in monkeys (*Macacus rhesus*) a disease closely simulating human measles. After an incubation period of 6 to 10 days, there developed a characteristic group of symptoms characterized by listlessness, drowsiness, leucopenia, catarrhal conjunctivitis, a rash on the labial mucosa, and a skin rash consisting of discrete red maculo-papules; fever was inconstant. Recovery occurred after an illness of 7 to 10 days; no respiratory complications were observed. The disease was transmitted from monkey to monkey by intratracheal inoculation of tissue suspensions (chiefly skin and buccal mucosa) of monkeys killed from 2–6 days after the onset of the reaction, and by intravenous inoculation with blood taken 7–13 days after infection; but it could not be carried on through monkeys indefinitely (Blake *et al.* 1936). Shaffer, Rake, Stokes and O'Neil (1941) inoculated children and monkeys—*Macacus mulatta*—simultaneously with blood drawn from human cases of measles in the early stages of the disease. Both sets of inoculations proved successful, the incubation period in the children varying from 5 to 12 days, in the monkeys from 6 to 16 days. The disease in the monkeys was generally milder than in the children,

and was not as a rule accompanied by either fever, cough, or coryza. Since Rake and Shaffer (1940) have found that nasopharyngeal washings are still infective after filtration through a Seitz EK disc, there seems little doubt that the disease must be due to a filtrable virus. As Enders (1941) points out, the monkey experiments would be more convincing if the disease could be transmitted back to man; so far this appears to have been done on only one or two occasions.

Numerous workers (Nevin and Bittman 1921, Duval and D'Aunoy 1922, Scott and Simon 1924, 1925) have claimed to have transmitted measles to *rabbits*. Their work is criticized by Purdy (1925), who completely failed to obtain any significant reaction in rabbits—even with material that was shown to be infective for monkeys. Taniguchi and his colleagues (1935) recorded the successful transmission of infection to *rabbits* and *guinea-pigs*, but there is reason to believe that the virus they established was not the measles virus, but one of the animal pox group (see Enders 1941). The evidence, on the whole, does not suggest that the disease has ever been successfully reproduced in animals, apart from monkeys.

Little is known about the virus.

Several workers have reported its cultivation on the chorio-allantoic membrane of the developing chick embryo, but most of the reports are unconvincing. More recently Rake and Shaffer (1940) state that they have been able to carry the virus through 20 serial egg passages and to reproduce infection with it in monkeys. Stokes and his colleagues (1943) were apparently able to transmit the disease in a modified form to children with virus that had reached its 66th serial egg passage, suggesting that the virus had undergone considerable attenuation in culture. Its growth in a tissue culture medium, consisting of Tyrode's solution, monkey serum, chick embryo tissue, and chicken plasma, has been reported by Plotz (1938) and confirmed by Rake, Shaffer and Jones (1941). In nasopharyngeal washings the virus is said to survive for several days at 0° C. or below, and to withstand 10 per cent. ether for at least 40 minutes (Rake and Shaffer 1940). Intranuclear inclusion bodies have been described by Broadhurst and her colleagues (1937, 1938) in the nasal mucosa, Koplik's spots, and white blood cells of measles patients, but their findings still await confirmation.

Prophylaxis.—General measures include notification, exclusion of children from school for a fortnight, and sometimes quarantine of non-immune contacts for 16 days. School closure is rarely called for; nor is it usually desirable to prevent healthy home contacts from attending school, provided that they are kept under observation. In view of the high complication rate due to cross-infection with hæmolytic streptococci, treatment at home rather than in hospital is advocated for patients with uncomplicated measles (see Wright 1945).

The prophylaxis of measles has been improved by the use of human *serum* from convalescent patients or from normal adults who have previously suffered from the disease. In children under 3 years of age, in weakly debilitated children, and in children suffering from some other serious disease, it is advisable to prevent an attack completely by injecting a fairly large dose of serum within 5 days of exposure to infection. The injection should be made intramuscularly, preferably into the vastus externus. The duration of the resulting immunity is 3–4 weeks, and the patient is subsequently susceptible to infection. After the age of 3 years it is desirable to aim, not at complete protection, but at attenuation of the attack. This is achieved by injecting the same quantity of serum within 6–9 days, or half the quantity within 1–5 days, of exposure to infection. The immunity following a modified attack appears to be permanent. The requisite dosage of serum is given in Table 191.

TABLE 191

DOSAGE OF SERUM IN MEASLES PROPHYLAXIS. (After Brincker 1936.)

Nature of Serum.	Limiting Dosage in ml.	Dosage Factor.	Route.	Prophylaxis.		Treatment.
				Protection.	Attenuation.	
Convalescent .	5–20	Age × 2	Intra-muscular	1–5 days	5–9 days	Within 6 days of onset.
Normal adult .	10–40	Age × 4	„	1–3 „	3–9 „	Dosage factor : age × 4.
Whole blood .	Double its dose as serum	Age × 4	„	1–3 „	3–9 „	Route intravenous.

Thus for a child under 3 years of age, 6 ml. of convalescent, or 12 ml. of normal adult, serum should be given for complete protection. For attenuation of the attack in a child of 6 years, 12 ml. of convalescent serum should be given between the 6th and 9th days after exposure, or 6 ml. between the 1st and 5th days. If adult serum is selected, double these quantities should be used. A fixed dose of 10 ml. of adult serum is used by some workers in preference to an age-adjusted dose ; if protection is desired it is given within the first 5 days, if attenuation is desired, within 6–9 days of exposure. Though this practice possesses the merit of simplicity it is doubtful whether it is altogether satisfactory (Gunn 1936). Convalescent serum should preferably be withdrawn from the donor 7–10 days after defervescence. Whole blood is of value mainly in general practice, when blood may be withdrawn from the mother or other member of the household and inoculated directly into the child.

For further information on the value of convalescent serum in prophylaxis reference may be made to the study of Stillerman, Marks and Thalhimer (1944).

Statistical analysis of the data so far accumulated has shown the undoubted value of serum prophylaxis (Report 1933, 1936, Hobson 1938). Convalescent serum is found to be more effective than normal adult serum, but only when administered to children under 5 years of age at an interval of less than 3 days after exposure to infection. It must be understood that to secure an attenuated attack, it is necessary not only to give serum, but also to make reasonably sure that the child has been adequately exposed to infection. Otherwise many children in whom it is desired to produce an attenuated attack resulting in lasting immunity may entirely fail to develop the disease and be left susceptible (Report 1936). For this purpose it is probably desirable to leave the child in contact with infection for a day or two and to delay giving serum for 5–9 days. (For further references to serum prophylaxis in measles see Zingher 1924, Debré *et al.* 1925, 1926, 1930, Copeman 1925, Toomey 1926, Haas and Blum 1926, Park and Freeman 1926, Benson and Lawrie 1927, Karelitz and Levin 1927, Kingsbury 1927, Gunn 1928, Benson 1929, Morales and Mandry 1930, Barenberg *et al.* 1930, Nabarro and Signy 1931, Gunn 1932, 1938.)

In place of serum the use of placental extract has been recommended by McKhann and Chu (1933) and McKhann (1937). In potency it occupies a place midway between convalescent and adult serum. The difficulty, however, of extraction of the placental globulins and the greater proportion of reactions to which it gives rise have not secured for it general acceptance.

The introduction of the gamma globulin fraction of human serum by Cohn and his colleagues (1944) bids fair to replace all other products in the serum prophylaxis of measles. The observations of Stokes, Maris and Gellis (1944) and of Ordman, Jennings and Janeway (1944) point to its high protective value; and the results obtained by Greenberg, Frant and Rutstein (1944) seem to show that a dose of 2 ml., given before the ninth day of exposure to infection, can be relied upon to afford complete protection to infants and children under 4 years of age. The reactions obtained to this "human immune serum globulin," as it is called, seem to be few and comparatively mild, and the small dosage required is likely to prove particularly attractive for the injection of infants and young children.

Unlike the Schultz-Charlton reaction in scarlet fever, no blanching of the morbilliform rash is produced by the inoculation of convalescent serum into the skin of a patient suffering from measles. If, however, 1–5 ml. of convalescent serum are injected subcutaneously at the beginning of the catarrhal stage, the appearance of the eruption is inhibited over an area some distance around the site of the needle puncture (Debré *et al.* 1923).

Vaccination against measles by an attenuated virus grown on the chorio-allantoic membrane of the developing chick embryo has been described by Maris and her colleagues (1943). A mild attack of the disease is said to be produced which apparently confers some protection against subsequent infection.

RUBELLA

SYNONYM: German Measles

Little is known about the causation of this disease. According to Hiro and Tasaka (1938) infection can be transmitted to susceptible children by subcutaneous inoculation of filtered nasal washings from patients in the acute stage. Habel (1942) has reported the reproduction of the disease in monkeys, *Macacus mulatta*, by the intranasal, subcutaneous, or intravenous inoculation of nasal washings or of blood taken within 24 hours of the appearance of the rash. After an incubation period of about 8–10 days the animals developed a leucopenia, fever, lymphocytosis, and a very light macular rash. Unfortunately, owing to circumstances, the nature of the experimental disease could not be proved by passage back to human beings. Some evidence was obtained to suggest that immunity following an attack may be slow in developing.

MUMPS

Mumps is an infectious disease of human beings characterized by a non-suppurative enlargement of the parotid glands, and sometimes of the testicles. It is commonest between 5 and 15 years of age, but often attacks young adult recruits to the fighting services. Most cases occur in the spring. The incubation period is usually 7–18 days. The disease seldom proves fatal, and even the encephalitis that occasionally accompanies it is usually benign. Second attacks are rare. Transmission appears to occur by droplets. There is some evidence that patients may be infective for a day or two before the parotitis becomes obvious. Isolation of patients should be maintained for a week after subsidence of the glandular swelling.

Though Kermorgant (1925) brought evidence to suggest that infection was caused by a spirochæte, there is now little doubt that the causative agent is a filtrable

virus. This conclusion, which was reached by Gordon in 1914 on the basis of monkey experiments, and by Wollstein in 1916 on the basis of experiments with cats, has received confirmation from the more recent experiments of Johnson and Goodpasture (1934, 1935), and Findlay and Clarke (1934). Saliva taken from patients in the early stage of the disease and inoculated into Stenson's duct, gives rise in *Macacus rhesus* monkeys to a disease similar to mumps. After an incubation period of 6–10 days or so, there is a rise of temperature, a leucopenia with a relative lymphocytosis, and a painful non-suppurative swelling of the parotid gland. Passage experiments can be made with a suspension of the ground-up glands filtered through a Berkefeld N candle. The intratesticular injection of such a filtrate gives rise in monkeys to a non-suppurative orchitis. Johnson and Goodpasture (1935) were able to transmit the disease back to human volunteers after it had been maintained for several generations in the monkey. Swan and Mawson (1943) succeeded in infecting monkeys by inoculation of cerebrospinal fluid from a patient suffering from encephalitis. According to Bloch (1937), the essential lesion of experimental parotitis in the monkey is focal acinar necrosis; œdema, hæmorrhage, and a lymphocytic reaction are said to be secondary manifestations. Transmission to rabbits has been claimed by many workers, but has so far not been confirmed (see Lépine *et al.* 1940).

The virus is resistant to freezing, drying, and glycerolation. It has not yet been cultivated, though mildly suggestive results on the chorio-allantoic membrane of the developing chick embryo have been reported by Swan and Mawson (1943).

According to Enders, Cohen and Kane (1945) complement-fixing antibodies appear in the serum of patients suffering from mumps and remain, though in diminishing quantity, for several months; their presence may be of value not only in the diagnosis of the parotitis itself, but in that of the meningo-encephalitis that sometimes occurs as a complication during or after an attack of mumps (Kane and Enders 1945).

Monkeys that have recovered from one attack of the disease are actively immune. Attempts to confer passive immunity to intraparotid infection by inoculation with the serum of persons who have recovered from mumps have so far proved a failure (Johnson and Goodpasture 1936). On the other hand, some degree of protection can be conferred on human beings by inoculation of convalescent serum within the first five days after exposure to infection. The dosage varies. Most workers suggest 2–3 ml., but Stillmunkès (1937) recommends 15–20 ml. The occasions on which serum prophylaxis of a non-fatal disease are required must be relatively few. For a general review of mumps, the reader is referred to the article by Wesselhoeft (1941).

YELLOW FEVER

Little was known about the ætiology of this once-dreaded disease till the studies of the American and the French Commissions were undertaken in the early years of this century.

The American workers, Reed, Carroll, Agramonte and Lazear (1900–01), at the beginning of the century, first showed that the blood of patients was infective during the first 3 days of the fever; that the infecting agent was able to pass through a Berkefeld filter; that the virus was destroyed in the blood by heating

to 55° C. for 10 minutes; that infection was not spread by contagion; that mosquitoes, *Aèdes ægypti* (also called *Aedes argenteus*, and *Stegomyia fasciata*) fed on patients during the first 3 days of the fever, became, after an interval of about 12 days, capable of transmitting the disease to normal persons; and that by the suppression of these insects, yellow fever could be brought under control.

Marchoux, Salimbeni and Simond (1903), likewise working with human volunteers, largely confirmed these results. They found, moreover, that the serum of patients during the first 3 days of the fever, but not later, proved infective to normal persons when injected subcutaneously in a dose of 0·1–1·0 ml.; that defibrinated blood kept at 24°–30° C. under a vaseline seal remained infective for 5, but not for 8 days; that the injection of blood kept for 8 days under these conditions was apparently able to produce some degree of immunity in human beings; and that the serum of convalescent patients appeared to be endowed with both prophylactic and therapeutic properties.

The natural outcome of these findings was to undertake an intensive anti-mosquito campaign. The result of this so far exceeded expectations that yellow fever was apparently wiped out of Central and South America. Ten years ago it was believed that the only serious remaining focus of infection was in West Africa. The work, however, of the past few years, carried out to a considerable extent under the auspices of the Rockefeller Foundation, has necessitated a complete revision of our ideas on the epidemiology of the disease. So far from having been wiped out in South America, it is now known that infection is widespread through large parts of the country, and that the disease occurs in an endemic form whose very existence had been previously unrecognized (Soper 1936, 1937, 1938). As has happened so often with other diseases, the more flagrant epidemic manifestations of the disease were allowed to obscure the less obvious but more persistent undercurrent of infection. The institution of routine post-mortem examinations of every person dying within 10 days of the onset of any disease—the so-called viscerotomy service (see Rickard 1937)—and the survey of different communities by the mouse-protection test (see below) to ascertain the frequency of specific serum antibodies against the yellow fever virus, showed that infection was far more widely distributed than had been realized, and that many persons must have been infected without ever developing the characteristic symptoms of the disease. It was found that, besides the urban type of yellow fever, which is carried by *Aëdes ægypti*, another type existed—provisionally referred to as **jungle yellow fever**—which occurred in districts entirely free from this species of mosquito.

It is too early yet to say very much about the epidemiology of this second type of the disease, but the evidence so far suggests that infection is maintained by certain species of tree-dwelling mosquitoes. *Hæmagogus capricorni* and *Aëdes leucocelaneus*, for example, have been found to harbour yellow fever virus (Shannon *et al.* 1938). *Hæmagogus* lives in the tree-tops during dry weather and is apparently able in rainy seasons to carry over infection from one year to the next. This probably explains why the disease is particularly liable to attack woodcutters (see Report 1940, 1941). It is known that several wild animals, including representatives of the primates, marsupials, edentates, and rodents, are susceptible to infection and not infrequently contain immune bodies in their blood. But the virus is present in the circulating blood for such a short time and immune bodies appear so rapidly that these animals cannot be regarded as affording a reservoir of infection in the strict sense. The real reservoir is the mosquito; the animals serve merely

as a convenient method of conveying infection from one mosquito to another (Bugher *et al.* 1944)

The disease is very restricted in its distribution by climate, occurring almost entirely within the tropics of Cancer and Capricorn. The endemic form occurs in both the Old World and the New. In Africa it occupies a band passing across the middle of the continent (Findlay 1941). In the New World the northern half of South America is affected. Why it has not so far invaded the Orient, where susceptible mosquitoes are abundant, is not clear. The incubation period of the disease is 3–6 days. A considerable proportion of the indigenous population of endemic areas develop only a latent or ambulant infection, after which they appear to be immune for life. Epidemics, when they occur, are never explosive, but are preceded for 2 or 3 weeks by a series of sporadic cases. They cease with the occurrence of the first frost (see Russell 1941).

Though there is reason to believe that rigid measures to diminish the prevalence of *A. ægypti* are likely to be successful in preventing the urban type of the disease, it is now clear that the eradication of infection by anti-mosquito measures alone is a hopeless task.

Animal Inoculation.—Stokes, Bauer and Hudson (1928), working in Nigeria, made a great advance when they found that Asiatic monkeys, in particular *Macacus rhesus*, could be experimentally infected with the virus of yellow fever, either by inoculation of virulent material, or by infected mosquitoes of the species *Aëdes ægypti*. Mosquitoes, when once infected, were found to be capable of transmitting the disease for the rest of their lives. It was shown that the bite of a single mosquito was sufficient to produce a fatal infection in a monkey. The virus in the circulating blood of monkeys was able to pass through Berkefeld V and N, but not through W, candles.

After subcutaneous inoculation of a *monkey* with infective material, there is an incubation period of 3 to 4 days, followed by a rise in temperature of about 3° F.; this temperature persists for 36 to 48 hours, and then falls suddenly to subnormal; collapse occurs, and the monkey dies about 5 to 6 days after inoculation. Post mortem, jaundice is usually present in some part of the body, especially the laryngeal mucosa and the subcutaneous fat; small hæmorrhages are frequently found, particularly in the lungs and alimentary canal, and in the wall of the stomach; dark coffee-ground material is often seen in the stomach and small intestine; the most constant feature, however, is the pale, mottled liver, which microscopically shows fatty degeneration and mid-zonal necrosis. The liver, when fresh, is highly infective for monkeys—in a dose of about 0·000,02 gm. When frozen, the liver remains virulent for about a fortnight; when dried and frozen, it remains virulent for about 3 months (Hindle 1929). This forms a very useful method of preserving the virus. The blood of infected monkeys contains enormous quantities of virus, proving infective sometimes in 1 : 50 – 1 : 100 million.

White *mice* are also susceptible to infection (see Theiler 1930, Dinger 1931). The intracerebral inoculation of these animals with 0·05 ml. of infective blood from a *rhesus* monkey gives rise, after an incubation period of 5 or 6 days, to an illness characterized by ruffling of the coat, inactivity, photophobia, paresis of the hind legs, tonic and clonic contractions of the whole body, and finally coma and death in 6–9 days. Post mortem there is an acute encephalitis, often with dilatation of the skin vessels, swelling of the lymph glands, hæmorrhages into the stomach, erosion of the gastric mucosa, fatty degeneration of the liver, and enlargement of the suprarenals. Infection can be carried on indefinitely by cerebral passage. According to Findlay and Clarke (1935*a*), an encephalitis may be set up in both monkeys and mice by the intranasal instillation of

a neurotropic strain of virus (see also Findlay and Stern 1935). *Guinea-pigs* can be infected intracerebrally, provided a neurotropic strain is used (Dinger *et al.* 1930, Mathis 1934, Lloyd and Mahaffy 1935).

Properties of Virus.—There is now no doubt that yellow fever is caused by a filtrable virus. Using gradocol membranes, Findlay and Broom (1933) have found that the virus is probably about 17–28 mμ in diameter. According to Pickels and Bauer (1940), who used the ultra-centrifuge method, it is only 12–19 mμ. Its successful cultivation in mouse embryo tissue was reported by Lloyd, Theiler and Ricci (1936). Jadin (1937) grew it on the chorio-allantoic membrane of hens' eggs; and Elmendorf and Smith (1937) simplified this procedure by direct inoculation of the virus into the chick embryo. When grown for several generations in tissue cultures, its virulence becomes modified; it no longer gives rise to a fatal disease when injected into monkeys subcutaneously, but it remains capable of killing mice inoculated intracerebrally (see Theiler and Smith 1937). Other changes can be produced by animal passage (see Sawyer *et al.* 1930, Findlay and Clarke 1935*b*, Findlay and MacCallum 1938). No antigenic differences have been recognized among strains of different origin. The virus contains a soluble antigenic material, which may be demonstrated as a precipitinogen in the serum of monkeys during the height of the illness (Hughes 1933). Survival of the virus in infected blood has already been referred to (see also Sawyer *et al.* 1929). It is killed by heat at 55° C. in 5 minutes, and rapidly dies in saline suspensions. In tissue, however, that is frozen solid, it remains alive for some weeks, and in tissue that is frozen and dried it retains its viability for years. It is readily inactivated by bile. In the liver of monkeys, less often of man, it gives rise to amorphous, acidophilic, nuclear degenerations. Though it is borne by mosquitoes, and may survive in them for the whole of their lifetime, there is no evidence to show that it can be hereditarily transmitted from one generation to the next (Philip 1929).

Diagnosis.—In the laboratory the diagnosis of yellow fever may be confirmed by intracerebral inoculation of the patient's blood during the first 3 days of the illness into mice. The mouse protection test (see below) may also be of value, if a specimen of serum can be obtained before the end of the first week and again in convalescence, in order to demonstrate the appearance of protective antibodies in the interval. The complement-fixation test may likewise be used early in convalescence. According to Lennette and Perlowagora (1943) complement-fixing bodies disappear fairly rapidly; their presence therefore is indicative of recent infection. For retrospective diagnosis, and for immunity surveys, the mouse protection test is used almost exclusively, since neutralizing antibodies are known to persist for years after an attack. Diagnosis at post mortem is made by histological examination of the liver, and confirmed if necessary by inoculation of the liver tissue intracerebrally into mice.

Prevention, Immunity and Vaccination.—In towns and even in country districts, where yellow fever is spread by *Aëdes ægypti*, the disease can be eradicated, as the workers of the Rockefeller Foundation have shown, by strict control measures designed to reduce the numbers of the mosquito vectors. *Aëdes ægypti* breeds not in ponds or pools, but in artificial water containers, where the natural enemies of the larvæ are fewest. It is a domesticated mosquito, and its control is therefore very much easier than it would otherwise be. In jungle yellow fever, however, anti-mosquito measures are impracticable and recourse has therefore to be had to vaccination of the exposed population.

The serum of convalescent patients and monkeys contains antibodies to the yellow fever virus, which may be demonstrated by the complement-fixation, the precipitation, or the mouse-protection test. This last test, which was elaborated by Sawyer and Lloyd (1931), consists in the intraperitoneal inoculation of mice with a fixed virus together with the serum to be tested; a simultaneous injection of starch solution is made into the brain to localize the virus. If the serum contains no antibodies, the animal dies of encephalitis. These tests, alone or in combination, have now been widely used in the survey of indigenous populations, and their results, as already mentioned, have shown the widespread distribution of infection in South America and West Africa (see Hughes and Sawyer 1932, Soper *et al.* 1932, Mahaffy *et al.* 1933, Beeuwkes and Mahaffy 1934).

The difficulty of eradicating infection completely by anti-mosquito measures has rendered some form of *vaccination* desirable for persons proceeding to endemic areas and for non-immune residents in endemic areas. Starting with the attempts of Hindle (1929), who used phenolized or formolized infected monkey liver and spleen, numerous vaccines have been developed. Since killed vaccines have met with no success (see Findlay and Mackenzie 1936), efforts have been made to find a strain of modified virulence that can be inoculated into human beings without danger. Sawyer, Kitchen and Lloyd (1932) introduced combined active and passive immunization, using a strain that had undergone variation as the result of repeated passage through the mouse's brain, together with human serum. An attenuated mouse passage virus, without serum, was recommended by Sellards and Laigret (1932, 1936); but though it has been used extensively on African natives, it has been generally regarded as too dangerous for human use. Later, a variant strain, 17D, was developed by American workers, which had been grown in tissue culture containing first mouse embryonic tissue, then whole chick embryo, and finally chick embryo from which the brain and cord had been removed. This strain was found to be greatly attenuated, failing to kill monkeys inoculated either subcutaneously or intracerebrally, and producing fatal encephalitis in mice after an average incubation period of 8 instead of 6 days; it still, however, retained its antigenic potency. Large quantities of vaccine could be prepared by inoculation of the variant strain into the developing chick embryo, incubating the eggs for 3–4 days, grinding up the embryo, suspending it in human serum, and clearing, freezing and drying the resulting mixture. For use the dried virus was rehydrated. The dosage for man was calculated according to the number of mice dying after intracerebral inoculation (Theiler and Smith 1937, Smith *et al.* 1938, Bugher and Smith 1944). This vaccine has been widely used, with excellent results. One drawback to it, however, is that occasional batches have given rise to jaundice, coming on, as a rule, 6 weeks to 4 months after inoculation (see Fox *et al.* 1942*b*). During the second world war, no fewer than 28,585 cases of jaundice occurred among the U.S. Army personnel between January and July, 1942, out of about 2½ million troops inoculated; 62 of these cases proved fatal (Report 1942*a*, *b*). There is little doubt that the jaundice was due, not to the yellow fever virus, but to the human serum used in the preparation of the vaccine (see p. 1794). Hargett, Burruss and Donovan (1943) have now prepared a similar vaccine from which the serum has been omitted. No jaundice has so far followed the use of this " aqueous base " vaccine; though Fox and his colleagues (1942*a*) have recorded a number of encephalitic reactions among those inoculated, which they attribute to variation in the 17D strain itself. The immunity conferred by the 17D chick

embryo vaccine lasts for at least 4 years and probably longer (Fox and Cabral 1943). The danger that vaccinated persons may serve to infect mosquitoes seems to be negligible, partly because the concentration of virus in the blood is very low, and partly because mosquitoes artificially infected with modified viruses of this type are unable to transmit the disease to susceptible animals (Roubaud *et al.* 1937, Smith *et al.* 1938, Whitman 1939). For an account of the ætiology, epidemiology and prevention of yellow fever, the reader is referred to articles by Sellards (1941), Russell (1941) and Gordon (1941).

Dengue Fever

Dengue fever is a disease of warm climates, and is peculiar to man; it occurs during the summer months, often in severe epidemic form, attacking a high proportion of the exposed population, and it is followed by a comparatively short-lived immunity. It is characterized by fever—usually of sudden onset and often of the saddle-back type—conjunctival congestion, pains, in the joints and muscles, leucopenia, and sometimes a rash. The disease lasts a week or ten days, and is seldom fatal. Ashburn and Craig (1907), working in the Philippines, brought evidence to show that infection was due to a filtrable virus carried by mosquitoes. By intravenous inoculation of volunteers with 20 minims of blood taken from dengue patients, they were able to reproduce the typical disease; the incubation period was as a rule 3 to 4 days—a little shorter than that of the natural disease, which is usually 4 to 8 days. Inoculation of two volunteers with blood filtered through a diatomaceous candle likewise reproduced the disease successfully. One volunteer out of four subjected to experiment developed the disease after being bitten by *Culex fatigans* Wied.

Cleland and Bradley (1918) in Australia found that the mosquito *Aëdes ægypti* was capable of transmitting infection. This observation was confirmed by Siler, Hall and Hitchens (1925) in the Philippines, who found that the patient was infective for the mosquito during the first 3 days of the disease, and that the mosquito did not become infective for human beings till the 11th day after biting. Once infected, the mosquito apparently remained so for the rest of its life. There is, however, no hereditary transmission of infection to the offspring. The mosquito, *Aëdes albopictus*, which is widely disseminated in the Far East, is also said to serve as a vector (Simmons *et al.* 1930). Observations in Greece showed that the disease could be transmitted by direct inoculation of filtered or unfiltered blood. The virus persisted in the blood for at least 5 days. The serum of patients remained virulent in sealed tubes for at least 54 days at 15°–18° C. Human volunteers inoculated subcutaneously with the ground-up bodies of *Aëdes ægypti* captured a week previously in the rooms of dengue patients, developed the disease 7–9 days later (Blanc and Caminopetros 1930, Pontano 1930). The virus passes through an L2 candle, and, according to Shortt, Rao and Swaminath (1936), can be cultivated on the chorio-allantoic membrane of the developing chick embryo.

Monkeys from non-endemic areas suffer from a very mild disease after inoculation, which is insufficiently characteristic for diagnosis. Their blood is said to be virulent for man 5–8 days, but not 12 days, after inoculation. Other laboratory animals seem to be insusceptible. In the diagnosis of dengue fever the severe leucopenia, with a proportional increase in the immature granulocytes, is of help. Second attacks of the disease are uncommon during any one epidemic. For a

general account of the disease see Simmons (1941) and the monograph by Lumley (1943).

Sandfly Fever

Synonym: Phlebotomus Fever.

This disease occurs in tropical and sub-tropical countries. It is characterized by an incubation period of 1–6 days, and a fever lasting at least 3 days, accompanied by severe headache, pains in the back, bones, joints, and muscles, and followed by considerable prostration. It is rarely fatal. Second, and even third, attacks do occur, but are not very common. The causative agent appears to be a filtrable virus. There is, however, some discrepancy of opinion on its properties. For instance, Shortt and his colleagues (1938) find that it is about 160 mμ in diameter, and that it can be grown in a tissue culture medium containing minced chick embryo, human serum and chick plasma, and on the chorio-allantoic membrane of the developing chick embryo (Shortt, Rao and Swaminath 1936). Sabin, Philip and Paul (1944), on the other hand, maintain that it is only 20–40 mμ in diameter and that it cannot be cultivated by the chorio-allantoic membrane technique. Again, according to Shortt and his colleagues (1940), the virus can be demonstrated in the patient's blood for a week in most cases, and occasionally for as long as 6 weeks. The time during which the serum is infective is given by the American observers as 3 days, namely for 1 day before to 2 days after the onset of the fever. Sera kept in the ice-chest remain virulent for months. As present in human blood, the virus, when inoculated into *rhesus* monkeys, gives rise to a mild fever; but the cultivated virus produces only a symptomless infection (Shortt *et al.* 1940). The incubation period after intracutaneous injection into human beings is said to be 2½ to 6 days (Sabin and Paul 1944). Neutralizing antibodies appear early in the serum of convalescent patients and of inoculated monkeys; they can be demonstrated by monkey protection tests, or by inhibition of the growth of the virus in culture. Immunity is said to persist for at least 4 months. Infection is spread by the sandfly *Phlebotomus papatasii* (see Whittingham 1924), though possibly other species may act as vectors. The flies do not become infective for 7–10 days after biting a patient with the fever. Diagnosis is often difficult. The absence of catarrhal symptoms is of help in distinguishing the disease from influenza, and the absence of rigors from malaria. Skin rashes do not occur (Walker and Dods 1941). The disease may closely simulate lymphocytic choriomeningitis, but the cell count in the cerebrospinal fluid is not increased (Pearson 1941). In the blood there is a leucopenia. Prophylaxis consists mainly in abolishing sandfly breeding grounds and in sleeping under a close-mesh net. Dimethyl phthalate and a pyrethrum vanishing cream are said to afford considerable protection against sandfly bites (Sabin and Paul 1944). Attempts at vaccination with living cultured virus have yielded inconclusive results (Shortt *et al.* 1940), but the use of a virus irradiated with ultra-violet light appears to be more promising (Sabin and Paul 1944).

Rift Valley Fever. Enzootic Hepatitis

In 1931 Daubney and Hudson described a new virus disease affecting sheep, cattle, goats, and man in the Rift Valley of Kenya Colony. In very young lambs the disease causes a mortality of 90 per cent. or over; but in ewes and cows the mortality is only 10–20 per cent. In man the disease resembles dengue fever,

and is characterized by malaise, nausea, rigors, abdominal discomfort, violent headache, transient fever, severe pains in the back and joints, and a leucocytosis followed by a leucopenia. Fatal cases are uncommon. By use of the mouse-protection test, the disease has now been shown to occur not only in Kenya, but in Anglo-Egyptian Sudan, in Uganda, and in the French Sudan (Findlay *et al.* 1936). In animals examined post mortem the principal finding is focal necrosis in the liver. Acidophilic intranuclear inclusion bodies can be demonstrated in the liver cells (Findlay 1933). The mode of spread of the disease is still in doubt. Daubney and Hudson (1933) bring some evidence to show that infection is carried by mosquitoes, but it is possible that it can also gain access by the respiratory tract (Francis and Magill 1935). Laboratory workers are not infrequently attacked.

Experimentally the disease can be transmitted to susceptible animals, including mice, monkeys and ferrets, but not guinea-pigs or rabbits, by cutaneous, subcutaneous, or intranasal inoculation. Mice are peculiarly susceptible, most of the animals dying in 36–96 hours after inoculation (Findlay 1932). By continued passage through the mouse's brain a neurotropic variant of the virus has been developed (Mackenzie *et al.* 1936).

The virus is widely distributed in the body, and can pass through the placenta to the fœtal organs. Its probable size is 23–35 mμ (Broom and Findlay 1933). In blood it is destroyed by exposure to a temperature of 56° C. for 40 minutes, but it survives contact with 0·5 per cent. phenol at 4° C. for 6 months. It can be cultivated in a minced chick embryo medium (Mackenzie 1933). An attack of the disease confers a high degree of immunity in sheep, and the serum of convalescent animals and human beings contains strong neutralizing and complement-fixing antibodies. Mice can be successfully immunized by a virus treated with formol or inactivated photodynamically with methylene blue (Mackenzie 1935).

An *epizootic hepato-enteritis* caused by a virus has been described in guinea-pigs (see Morcos 1933).

Bornholm Disease

Synonyms: Epidemic Myalgia, Epidemic Pleurodynia.

Though this disease has not yet been shown to be caused by a virus, a brief description of it may be given here. It is characterized by acute pain, usually of sudden onset, affecting the chest, upper abdomen, or lower region of the back on one or both sides, fever, often headache, little or no constitutional disturbance, an absence of catarrh, and a tendency to relapse. The pain is paroxysmal, and lasts for a day or more. The muscles are tender on pressure. Relapses are common at intervals of 2 or 3 days, or after a longer period. No characteristic changes occur in the blood. Fatal cases are rare. The incubation period is 2–4 days. The disease occurs in epidemic form, usually in the late summer. Infection spreads probably by contact. The disease has been observed in various parts of the world. The Danish physician Sylvest (1934), who studied an outbreak in Bornholm in 1930, has written a monograph on the disease, to which reference may be made.

Epidemic myalgia of the neck and shoulders has been described by various observers (see Beeson and Scott 1942). It differs from the Bornholm disease in not affecting the respiratory muscles of the chest and abdomen, and in being accompanied by little or no fever. Its duration is usually less than 5 days. Recurrent attacks are not uncommon, and in occasional cases the disease becomes chronic

and may pass into generalized fibrositis. Beeson and Scott have apparently been able to transmit the disease to healthy human volunteers by intravenous inoculation with blood taken from patients on the second day of the illness. The incubation period of the experimental disease was 2–4 days.

Durand's Disease

Durand (1940) described a febrile disease in himself, which he showed to be caused by a virus. Findlay (1942), who likewise contracted the disease while working with the virus in the laboratory, suggested the name Durand's disease. The symptomatology appears to be variable. Fever lasts about 10 days, and is accompanied by headache, and sometimes by symptoms of meningeal, upper respiratory or gastric inflammation. Blood taken during the fever is infective for guinea-pigs; occasionally the urine or cerebrospinal fluid may also be shown to contain the virus. Guinea-pigs are susceptible to inoculation by practically any route. After subcutaneous injection there is an incubation period of about 6–10 days, which after one or two passages of the virus falls to 2–5 days. There is fever lasting 6–10 days, local enlargement of the lymph nodes, dyspnœa, severe loss of weight, and a leucopenia after a preliminary leucocytosis. Only about 10 per cent. of the animals die—usually after 3–4 weeks. Animals killed a week or so after the onset of the fever show emaciation, a local hæmorrhagic gelatinous œdema, great enlargement of the spleen, some degree of interstitial pneumonia, and sometimes a brownish-yellow discoloration of the liver. The virus is present in the blood and organs. Intratesticular inoculation of guinea-pigs produces an orchitis. Animals that recover from the disease are immune. Cats, dogs, and *rhesus* monkeys show some meningeal reaction after intracerebral inoculation, but most other animals develop only a latent infection. Two human patients inoculated subcutaneously by Durand for purposes of pyrotherapy became febrile in 4 days; fever lasted 8 days. There were few symptoms, other than a meningeal reaction in one of the patients. The virus is estimated to be 38–57 mμ in diameter. It can be grown in serum Tyrode chick embryo tissue culture medium, and on the chorio-allantoic membrane of the developing chick embryo. In infected spleen it remains virulent for about 18 days at 4° C., and when frozen and dried for about a year. It is killed by exposure to a temperature of 65° C. for 30 minutes. No cross-immunity can be demonstrated between Durand's disease and either lymphogranuloma or lymphocytic choriomeningitis.

Distemper

Distemper is an acute infectious disease of young carnivorous animals. It is very common in puppies, and has given rise to great trouble in foxes reared for the fur industry. In the dog the disease is characterized by an incubation period of 3–6 days, an initial coryza, fever of a peculiar type, severe gastro-intestinal disturbance, and catarrhal inflammation of the respiratory tract often passing on to pneumonia. Encephalitis is a less common complication. The disease normally lasts 2–4 weeks and has a low mortality; but complicated cases, which probably constitute 40 or 50 per cent. of all cases, may last for several weeks and are accompanied by a mortality running up to 80 per cent. The disease is said to be characterized by acute anæmia and hypoglycæmia (Wharton and Wharton 1934). The encephalomyelitis that is sometimes observed is regarded by Perdrau and Pugh (1930) as being caused by a virus different from the distemper virus,

mainly because of the demyelination that is present (see p. 1921). Verlinde (1939), however, recognizes two types of encephalitis, one caused by the distemper virus itself, and another by a specifically neurotropic virus, which may cause encephalitis in the absence of distemper. The disease is spread by contact with infective secretions and discharges.

Distemper occurs naturally in the ferret, and is characterized by an incubation period of about 10 days, an initial coryza, and the formation of vesicles and pustules around the mouth ; just as in dogs, encephalitis may develop in a small proportion of cases. Distemper in the ferret is a very fatal disease, causing a mortality of about 90 per cent. (Dunkin and Laidlaw 1926). The disease has been studied to a limited extent in the cat (Hindle and Findlay 1933, Dalling 1931), the fitch (Dalling 1931*b*), and the fox (Dalling 1932*a*). In cats it seems to be due to an entirely different virus from that infecting dogs, belonging to the lymphogranuloma-psittacosis group (see p. 1877).

Distemper can be experimentally reproduced in dogs or ferrets by the subcutaneous inoculation of infective material, such as blood or spleen. Carré (1905) was able to transmit the disease to young puppies by bacteria-free exudates and by bacteria-free filtrates of infective discharges. Though M'Gowan (1911) in Scotland, and Ferry (1911) and Torrey and Rahe (1913) in America, brought forward evidence to suggest that distemper was caused by *H. bronchisepticus* (see Chapter 33), the more recent work of Dunkin and Laidlaw (1926) and of Laidlaw and Dunkin (1928) leaves no doubt that the primary cause of distemper is a filtrable virus. These workers were able to transmit the disease to dogs and ferrets by infected blood and serum from which no bacteria could be cultivated, and by Mandler filtrates of ground-up ferret's spleen. The disease reproduced by these bacteriologically sterile inocula was identical with natural distemper. Laidlaw and Dunkin regard *H. bronchisepticus* as a secondary infective agent responsible for the respiratory complications of the disease ; they draw attention to the fact that in natural distemper, in which pneumonia is not uncommon, *H. bronchisepticus*, though readily cultivable from the lung, can rarely be cultivated from the blood, thus indicating that the organism is a secondary rather than a primary invader.

The virus can be grown in tissue culture. It is present in the blood of ferrets during the first 4 days of the disease, and in the blood of dogs at the height of the first febrile period. In the tissues it gives rise to cytoplasmic and intranuclear inclusion bodies, principally in the epithelial lining of the respiratory system, urinary tract, bile ducts, and ducts of the salivary and pancreatic glands (Green and Evans 1939*a*). Their histological demonstration in the bladder, nose, or trachea affords a rapid method of diagnosis (Green and Evans 1939*b*).

Vaccination.—Laidlaw and Dunkin (1928) were able to immunize ferrets and dogs by a specific formolized vaccine. They found that 2 ml. of a 20 per cent. suspension of a ferret's spleen treated with 0·1 per cent. formol, when injected subcutaneously, would protect normal ferrets against a large dose of active virus given 2 weeks later. A similar formolized vaccine made from infected dog's liver, spleen, and lymph glands, when given in a single dose to dogs, and followed by the inoculation of an attenuated living strain of virus, produced complete immunity. It is noteworthy that vaccine made from ferret's tissues had little protective action on dogs, unless multiple injections were given ; and that vaccine made from dog's tissues had practically no protective action on ferrets, even when multiple injections were given. The vaccine has been tested under field conditions and has given

very satisfactory results. It is now made from the spleen and mesenteric lymph nodes of dogs (Laidlaw and Dunkin 1932). Experience has shown that the original "wet virus," used for the second dose is unsuitable for commercial distribution, and it has been replaced by a stable dried form of ferret virus (Dalling 1931*a*, 1932*b*). Some workers prefer to give two doses of the dog vaccine at a week's interval followed by the living virus a fortnight later (Kelser 1941). Immunization with a single dose of serum-virus mixture proved unsatisfactory and was given up (Dalling 1932*b*). If, however, a fully virulent dried ferret virus is inoculated, followed 1–2 hours later by a dose of immune serum, a satisfactory immunity results. This method is extensively used in practice in order to save the veterinarian two visits. For treatment of the disease immune dog serum may be used. It is said to be of considerable value if given within 7 days of the onset of symptoms (Wright 1932). It is also useful for prophylaxis.

Feline Enteritis

A widespread highly contagious disease of cats occurs in the United States to which the name feline enteritis is often given. It has been studied by Hammon and Enders (1939) and by Syverton and Lawrence and their colleagues (Syverton *et al.* 1943, Lawrence *et al.* 1943). Though the accounts of these observers differ to some extent, there is little doubt that they were dealing with the same disease. Kittens and young cats seem to be mainly affected. The incubation period is 4–7 days. The symptomatology is irregular, but listlessness, prostration, anorexia, vomiting, and diarrhœa are often present. The temperature is raised, and nasal and ocular discharges are common. The most characteristic feature, however, is the occurrence of a profound leucopenia, amounting sometimes to almost complete absence of white cells from the circulating blood. Death usually occurs in 2–4 days. The case mortality is given as 50 per cent. At post mortem there is little macroscopic evidence of disease ; but microscopically there is severe aplasia of the cellular elements of the bone marrow, and conspicuous intranuclear inclusion bodies are found in the epithelial cells of the intestinal mucosa and the reticular cells of the spleen and lymph nodes. Infection is spread by contact with infective discharges. A virus, capable of passing through a Berkefeld W filter, and therefore probably not greater than 35 mμ in diameter, can be demonstrated by animal inoculation in the blood, organs, nasal secretion, fæces, and sometimes urine of infected animals. The disease can be reproduced experimentally by inoculation of non-immune animals by the oral, intranasal, subcutaneous, and intravenous routes. Attempts to cultivate the virus have so far failed. The virus is specific for cats, and is apparently distinct from the feline distemper virus, but further observations are required. Recovery from the disease is accompanied by the appearance of specific neutralizing and protective antibodies.

Swine Fever

Synonyms : Hog Cholera. *Schweinepest* (German). *Peste du porc* (French).

Swine fever or hog cholera is an infectious disease, peculiar to pigs, caused by a filtrable virus. It is widespread throughout the world ; a special form of the disease has been described by Montgomery (1921) in East Africa. The disease is primarily a septicæmia, but in a large proportion of cases intestinal compli-

cations develop due to *Salm. choleræ-suis* or other members of the animal paratyphoid group, or lung complications due to *Pasteurella suiseptica*. A great deal of confusion has occurred in the past with regard to this disease, which was originally believed by Salmon and T. Smith (1886, 1885-95) to be due to infection with *Salm. choleræ-suis*; but it now appears to be fairly certain that there are at least three infections which may occur singly or concurrently. (1) Swine fever; this is due to a filtrable virus. (2) Paratyphoid of pigs; this is an intestinal disease caused by *Salm. choleræ-suis*. (3) Swine plague, this is a pleuropneumonia caused by *Pasteurella suiseptica*. The confusion has resulted from the fact that in swine fever secondary invasion with *Salm. choleræ-suis* or *Past. suiseptica* is very common.

The evidence that swine fever is primarily due to a filtrable virus was first advanced by de Schweinitz and Dorset (1903), and may be summarized as follows (Uhlenhuth and Haendel 1913): (1) Filtered blood, serum, organ suspensions, bile, or urine, when inoculated in 1–2 ml. doses, are able to give rise to the disease in normal pigs after an incubation period of about 8 to 10 days. (2) The disease may be carried over by passage from animal to animal by inoculation of filtered blood. (3) Animals that have withstood the inoculation of filtered blood are henceforward immune both to natural and experimental infection. (4) Swine that have passed through an attack of the natural disease are resistant to the inoculation of filtered blood. (5) Normal swine placed in contact with experimentally infected swine develop the disease. (6) Animals injected intravenously or fed with cultures of *Salm. choleræ-suis* develop acute intestinal inflammation, similar to that occurring in swine fever, but the filtered blood of these animals is not infective to normal swine. (7) Normal animals placed in contact with animals infected with *Salm. choleræ-suis* do not contract swine fever. (8) Animals that have overcome an infection with *Salm. choleræ-suis* are not immune to swine fever. (9) *Salm. choleræ-suis* is not demonstrable in more than a variable proportion of cases of swine fever.

Natural infection in swine fever appears to occur by ingestion of infective material, especially material contaminated with the urine of sick animals (Hutyra and Marek 1926). Animals that have recovered from the disease may continue to carry infection for weeks or months, the virus apparently persisting in the button ulcers of the intestine (Gibbs 1933).

The virus is unusually resistant to inimical agencies. In filtered blood it is said to withstand a temperature of 58° C. for 2 hours, but to be destroyed by a temperature of 78° C. maintained for 1 hour. Fluid material containing the virus retains its virulence at room temperature for 10 to 14 weeks, and dried on brick or hay for at least 28 days (Slavin 1938). In serum the virus is destroyed by 2 per cent. formol in 15 days, and by 2·5 per cent. antiformin in 2 hours (Hutyra and Marek 1926). It can be grown in tissue culture, preferably containing fresh minced pig testicle, on the chorio-allantoic membrane of the developing chick embryo, and on the surface of swine serum agar if the inoculum is previously mixed with fresh testicular cells (Hecke 1932, Tenbroeck 1941).

Attempts to confer an active immunity on swine by the injection of killed virus have failed. In practice, immunity can be produced by the simultaneous injection of 20 ml. immune serum, taken from an animal that has recovered from the disease, and 1–2 ml. of defibrinated virulent blood. Animals treated by this method are immune for life. (See also Donatien and Lestoquard 1929.)

Rinderpest or Cattle Plague

Rinderpest is an acute infectious disease of cattle, characterized by an incubation period of 3 to 9 days, acute fever lasting for 4 to 7 days, inflammation of the oral and gastric mucosa often attended by necrosis and ulceration, and a mortality varying from 15 to 75 per cent. The disease is prevalent in Southern Europe, Asia, and Africa. It also attacks buffaloes (Schein 1917). The existence of chronic carriers, with diphtheritic ulcers in the abomasum, has been recorded by Gibbs (1933).

Inoculation of normal animals with tissue fluids from an infected animal reproduces the disease. At the height of the attack the blood proves virulent in a dose of 1/1,000 to 1/25,000 ml. (Schein 1917). Goats are susceptible to experimental infection, but continuous passage through these animals is said to be followed by a diminution in virulence of the virus. There is evidence that the virus is contained chiefly within the leucocytes. Thus in blood that is allowed to clot naturally the serum is avirulent; in defibrinated blood that is centrifuged the deposit alone is virulent; in blood laked with distilled water, and centrifuged, the deposit, which consists mainly of leucocytes, alone is virulent (Kolle, see Nicolle and Adil-Bey 1902; Schein 1917, Daubney 1928). Nicolle and Adil-Bey (1902) brought forward evidence to show that the virus, when present in diluted tissue fluids or suspensions, may pass through a Berkefeld N or a Chamberland F candle; the results however are inconstant—possibly because of the intracellular location of the virus. The virus has not yet been cultivated, but Minett (1923) found that it could remain alive for at least 6 days at 37° C. in citrated blood, and for at least 13 days at 39°–40° C. in a glucose ox blood peptone water medium layered with paraffin.

Cattle may be immunized against the disease by the simultaneous injection of immune serum and living virus. In buffaloes this method is unsatisfactory, unless a large amount of serum combined with the least possible amount of virus is used (Schein 1917). Daubney (1928) states that formolized vaccines prepared from spleen pulp confer a high degree of immunity upon inoculated animals, but field inoculations with these vaccines have not yet been carried out. Pfaff (1938) recommends a vaccine made from dried goat spleen. Immunity is said to be established within 48 hours. This method has been used extensively on cattle and buffaloes, with promising results.

African Horse Sickness

African horse sickness is a highly infectious disease of horses and mules, characterized in the acute form by fever, general symptoms of illness, and pulmonary œdema; in the subacute form by fever, constitutional symptoms, and the development of subcutaneous œdematous swellings around the orbits, and not infrequently on the forehead, head, chest, abdomen, back, and extremities. The incubation period is about 6 to 7 days. In South Africa the disease occurs annually during the rainy, warmer months, January to March, especially in low moist localities, and is accompanied by a high mortality. Natural infection is probably carried by mosquitoes (Hutyra and Marek 1926). The disease can be reproduced experimentally in horses by the subcutaneous or intravenous inoculation of small quantities of blood taken from infected animals. Blood, when diluted with saline, and filtered through a Berkefeld or Chamberland candle, still proves infective. More

than one type of virus appears to exist. Prophylactic inoculation may be accomplished by Theiler's method, which consists in the injection of large quantities of immune serum intravenously, together with small quantities of virulent blood subcutaneously, followed by a second serum injection after the appearance of the febrile reaction. More recently, a specially developed neurotropic virus has been used.

Infectious Anæmia of Horses

Synonym: Swamp Fever.

This disease, which is not to be confused with the swamp fever of human beings caused by *Leptospira grippo-typhosa* (see Chapter 82), has a wide geographical distribution, occurring in various parts of Europe, the United States, Canada, Japan, and South Africa. It is most prevalent in low-lying badly drained districts, and reaches its maximum incidence during the summer months. The disease was shown by Vallée and Carré (1904) to be due to a filtrable virus, which is constantly present in the blood stream. By the gradocol membrane technique its size appears to lie between 18 and 50 $m\mu$ (Balozet 1939). Transmission probably occurs by biting flies—*Stomoxys calcitrans*. The disease can be reproduced experimentally by biting insects, but not by contact or feeding. Equines are alone susceptible; laboratory animals are refractory. The disease may be acute or chronic. The acute form is characterized by fever, extreme weakness, and conjunctival hæmorrhages, the chronic form by general unthriftiness with extreme emaciation. Anæmia does not appear to be a prominent sign. Death may occur in acute cases. Horses may remain carriers for years. There is, as yet, no specific diagnostic test or therapeutic treatment for the disease (for references see Stein 1935).

Malignant Catarrh of Cattle

Synonym: *Snotsiekte.*

This disease occurs in various parts of the world, and is characterized by fever, catarrh of the oral, nasopharyngeal, and conjunctival membranes, general enlargement of the lymphatic glands, and often symptoms suggesting involvement of the brain or cord. The mortality is subject to considerable variation. Post mortem examination of fatal cases often reveals petechial hæmorrhages in the stomach, mottling of the liver and kidneys, congestion and petechiæ in the respiratory mucosa, œdema of the lungs, enlargement of the lymphatic glands, and sometimes plate-like extravasations of blood on the surface of the brain. The disease is apparently caused by a virus, which can be transferred to rabbits and back again to cattle (see Daubney and Hudson 1936).

Ephemeral Fever of Cattle

Synonym: Three-day Sickness.

This disease is widely distributed in tropical and sub-tropical parts of the Old World. When it was introduced into Australia in 1936, it swept through the country like a pestilence. It is characterized clinically by an incubation period of 2–10 days—most commonly 3 days—sudden onset, high fever, anorexia, shivering, and frequently lameness and nasal discharge. Recovery is rapid;

relapses are uncommon ; mortality is low ; and the commonest sequela is prolonged locomotor disturbance. Blood is infective from the latter part of the incubation period to the fourth day after subsidence of the fever. The virus, which passes through a gradocol membrane of A.P.D. 0·7 μ, is associated in the blood with the leucocyte-platelet fraction. Kept at 0° C., blood remains infective for 7 weeks, and when dried and frozen for over 12 weeks. The disease can be reproduced in cattle by intravenous inoculation of infected blood. Other animals are resistant. The natural mode of spread is unknown, but sandflies are suspected. The disease leaves behind it a solid immunity. In many respects ephemeral fever of cattle resembles dengue fever in man (for references see Curasson 1936, Mackerras *et al.* 1940).

Blue-tongue of Sheep

Synonym : Catarrhal fever of sheep.

This is a specific disease affecting sheep in South Africa. It is characterized by an incubation period of about 4 days, fever lasting 5–7 days, and a catarrhal inflammation of the mucous membranes of the mouth, lips, tongue, upper air passages, and alimentary canal, and often of the laminæ and coronary band of the feet. The distinctive lesions in the mouth, which give the disease its name, do not appear for 7–10 days. The case mortality varies greatly. Blood is infective, even after passage through Berkefeld candles and after storage for 2 or 3 months under sterile conditions. The disease can be reproduced in sheep by parenteral inoculation. Infection is supposed to spread naturally by insects. Immunity can be conferred on sheep by inoculation with an attenuated virus—Theiler's vaccine (see Spreull 1913).

Nairobi Disease of Sheep and Goats

We owe most of our information on this disease to Montgomery, (1917), who studied it naturally and experimentally. It occurs enzootically among sheep and goats in the Kikuyu country, becoming epizootic when large numbers of susceptible animals are brought together. Sheep are more prone to the disease than goats, and—curiously enough—native sheep are more susceptible than pure-bred animals. The disease is characterized by an incubation period of about 2 days, a sudden rise of temperature to 105°–108° F., a fall to normal in 2 days followed by obvious illness, diarrhœa with sometimes blood and mucus in the stools, and—in fatal cases—death within 2–4 days of the onset of obvious symptoms. At post mortem there is an acute hæmorrhagic gastro-enteritis, the spleen is enlarged, the gall bladder is distended with bile, and the trachea is congested and may contain blood-stained mucus. The case mortality in native sheep is about 70 per cent. The blood is infective during the fever and for a day after its fall. The infectivity is retained after passage through a Chamberland F candle. Though the urine may also contain the virus, infection does not appear to spread by contact, but is transmitted by the bite of the " brown " tick, *Rhipicephalus appendiculatus*. Ticks can be infected in the nymphal as well as the adult stage, and there is some evidence to suggest that hereditary transmission of the infection may occur. Immunity to the disease persists for, at any rate, some months. No method of artificial immunization has yet proved satisfactory. The " brown " tick is also responsible for carrying East Coast fever in cattle. Dipping cattle

at a 3-day interval will help to clear the ground of ticks, and so diminish the risk to sheep of infection with the virus of the Nairobi disease.

Epizootic Abortion of Mares

In addition to infection with *Salm. abortus-equi* or with streptococci, a form of epizootic abortion of mares has been described that appears to be caused by a virus. The disease is very contagious. Abortion occurs, after profuse sweating but no other clinical symptoms, at the 9th to 11th month. There is a slight vaginal discharge of short duration, with rapid and complete recovery of the mare. Dimock and Edwards (1936) observed several outbreaks in the United States. No bacterial cause could be found. In many of the aborted fœtuses there was a clear yellow or reddish-yellow exudate in the pleural cavity, numerous small white foci of degeneration in the liver just beneath the capsule, congestion of the mesenteric and colonic lymph nodes, and petechial and lineal hæmorrhages in the heart. Pregnant mares, fed on fluids and tissues from infected fœtuses, either before or after Seitz filtration, aborted in 18 to 34 days. Dimock and Edwards obtained doubtful results in their attempted transmission of the disease to guinea-pigs, but Miessner and Harms (1937) in Germany were apparently more successful. By subcutaneous and intraperitoneal inoculation of filtered material from the liver, spleen, kidneys, and stomach contents of aborted fœtuses, they were able to reproduce the disease in pregnant guinea-pigs, and to carry on infection through 4 passages.

Fowl Plague or Fowl Pest

This is an acute infectious disease of fowls, and exceptionally of geese, which was studied by Landsteiner (1906) and Russ (1906). It does not appear to spread by contact, and the natural mode of infection is unknown. The incubation period is 3–5 days; the symptoms consist of depression and dullness, darkening of the comb and wattles, and inflammation of the buccal mucosa. The disease lasts 2–4 days, and is very frequently fatal (Hutyra and Marek 1926). The experimental disease may be produced in chickens by the inoculation of blood, nasal secretion, or cloacal secretion in minimal quantities. Pigeons are resistant. The minimal infecting dose of fowls' blood is seldom above 0·000,000,1 ml. Ferrets and *rhesus* monkeys are said to show some degree of susceptibility (Findlay and Mackenzie 1937). The virus is able to pass through porcelain candles, and according to Elford and Todd (1933) is 60–90 mμ in diameter. Todd (1928*a*) finds that in the centrifuged blood of infected fowls the virus is contained chiefly in the leucocytic layer, the concentration in this layer being roughly 100 times that in the clear plasma or washed red blood corpuscles. Doerr and Gold (1932), however, disagree with this, and bring evidence to show that the virus is adsorbed on to the red cells (see also Doerr and Seidenberg 1932). Attempts to cultivate the virus in defibrinated fowl blood have been unsuccessful, but Burnet and Ferry (1934) have grown it on the chorio-allantoic membrane of the developing chick embryo. In contrast to the Newcastle disease virus (see below), no focal lesions are found in egg cultures. Immunization experiments have been disappointing. Todd (1928*b*) was able to protect fowls against at least 300,000 lethal doses by giving three injections at weekly intervals of a phenolized vaccine, but his results still await confirmation. Heated or formolized vaccines both proved unsatisfactory.

Whether the plague affecting birds of the *thrush* family, described by Maggiora and Valenti (1903), is related to fowl plague is uncertain.

Newcastle Disease of Fowls

This disease, which was described by Doyle in 1927, was first observed on a poultry farm near Newcastle-on-Tyne, but has since been reported from many parts of the world. It is an acute, febrile, contagious disease of fowls, which resembles fowl plague, but differs from it in a number of particulars. In addition to general symptoms of sickness, there is an offensive watery diarrhœa, a mucous discharge from the nostrils and mouth, and, most characteristic of all, difficulty in respiration manifested by the long gasping inhalation through the half-opened beak. The incubation period is 4–11 days. The morbidity in infected flocks is very high, and the case mortality verges on 100 per cent. The disease can be readily transmitted not only to fowls, but also to pigeons, which it will be remembered are insusceptible to fowl plague. The causative agent is a virus, which, according to Burnet and Ferry (1931), is 80–120 mμ in diameter, and can be readily cultivated on the chorio-allantoic membrane of the developing chick embryo. The virus kills the embryo in 24–72 hours; post mortem, hæmorrhagic encephalitis and hæmorrhagic lesions, particularly in the developing feather follicles, are striking features (Burnet 1942). Inoculated by the allantoic route, it multiplies abundantly, and the allantoic fluid gives the Hirst agglutination reaction with chicken red blood corpuscles. After intranasal inoculation into mice, it produces consolidation of the lungs. In these and some other ways the Newcastle virus closely resembles the influenza virus of man. It is not, however, pathogenic for ferrets, nor does it appear to be antigenically related to the virus of influenza (Burnet 1942), though it behaves like it in many important respects and has in fact been responsible for one case of human infection (Burnet 1943). It is found in the body fluids, organs, and excretions of affected birds. Cross-immunization tests show that the fowl plague and Newcastle viruses are distinct.

Infectious Laryngo-tracheitis of Fowls

This disease has so far been reported mainly from North America and Australia. It appears to have been first recognized and studied in the United States by May and Tittsler (1925), Beach (1931), and others. Hyperacute, acute, chronic and asymptomatic forms are recognized clinically (Seddon and Hart 1935). Affected birds suffer from difficulty in respiration. The head is elevated, the neck extended, and air is drawn in through the half-opened beak with a loud wheezing sound. During expiration the head is lowered, and violent fits of coughing may occur, accompanied by the expulsion of masses of clotted blood and mucus. Fowls of all ages are susceptible. The incubation period is 7–12 days. The morbidity in an infected herd is 50–90 per cent. The case mortality varies in different outbreaks from 5–90 per cent. averaging about 20 per cent. (Doyle 1933). The disease is contagious, and there is evidence that chronic carriers may play a part in keeping infection alive from one outbreak to the next (Gibbs 1933). Intratracheal inoculation of infective material into normal fowls readily sets up the disease, but pigeons are resistant (Seddon and Hart 1936). The causative agent appears to be a virus, which is said by Gibbs (1935) to pass through a membrane with an average pore diameter of 0·082 μ. This means that the virus is smaller than that of fowl plague or the Newcastle disease. Burnet (1936) has cultivated the virus on the chorio-allantoic membrane of the chick embryo, on which under suitable conditions it gives rise to pocks. By counting the number of pocks developing after inoculation

with mixtures of virus and immune serum, he has been able to study the process of serum neutralization. The results suggest that epizootic strains are more readily neutralizable by serum than enzootic strains, even though no qualitative antigenic difference may be detectable between the two strains. According to Brandly (1937) the fowl-pox virus can develop on the chorio-allantoic membrane of the eggs of the chicken, turkey, duck, guinea-fowl, and pigeon, whereas the laryngo-tracheitis virus will grow in the chicken and turkey egg, but not in the duck, guinea-fowl, or pigeon egg. Fowls may be actively immunized against the disease by inoculation of virulent material into the cloaca and bursa of Fabricius. The resulting lesions are not serious, and leave behind them a substantial degree of immunity (Beaudette and Hudson 1933). The best time to vaccinate is between the age of 16 and 20 weeks (Gibbs 1936). For the differential diagnosis of the disease from fowl-pox, coryza, and A-avitaminosis, the reader is referred to Seddon and Hart (1935).

Kligler and Perek (1942) have described a disease among chicks in Palestine, resembling infectious laryngo-tracheitis but differing from it in its mildness. The disease spreads readily by contact, and can be reproduced experimentally by intratracheal or intraperitoneal inoculation with a Seitz filtrate of lung or tracheal mucus. The virus is present on the surface of the eggshell, where it can be destroyed by permanganate.

Infectious Bronchitis of Chickens

Beaudette and Hudson (1937) have described an epizootic disease which they think has probably been confused in the past with infectious laryngo-tracheitis. It affects young chicks—usually less than a fortnight old—is characterized by symptoms similar to those of laryngo-tracheitis, and is accompanied by a high mortality. At post mortem, the bronchi contain thick mucus or cheesy plugs, the abdominal air-sacs are turbid, and there is a fibrinous exudate in the pericardial cavity. The virus passes a Berkefeld W filter. It produces the disease on intratracheal or intranasal inoculation into young chicks, but not with regularity on subcutaneous or intramuscular inoculation. After a few passages, it grows well on the chorio-allantoic membrane of the developing chick embryo, but unlike the virus of Newcastle disease or of laryngo-tracheitis, it gives rise to no focal lesions; the embryo, however, is killed. Serum from convalescent birds contains neutralizing antibodies. There is no cross-immunity between infectious bronchitis and laryngo-tracheitis.

Blue Comb of Chickens

Synonyms: Pullet disease, X Disease.

This disease has been observed in the north Atlantic and north central area of the United States. It affects pullets mainly 5–7 months of age, though chicks only 4 weeks old may be attacked. Turkeys may also suffer. The incidence is highest in the summer months. The morbidity and mortality in a flock are very variable. According to Jungherr and Levine (1941), who described the disease, the morbidity varies from 0·1 to 100 per cent. with a mean of about 20 per cent., and the case mortality from 0·2 to 53 per cent. with a mean of about 5 per cent. The disease is characterized by a fall in egg production and food consumption, darkening of the comb, droopiness, cyanosis, dehydration, diarrhœa or constipation,

and occasionally pyrexia. Pathologically, the chief lesions are focal necrosis of the liver, serous petechiæ, enlargement of the pancreatic islands, patchy muscular degeneration, and nephrotic changes in the renal glomeruli and tubules. Jungherr and Levine regarded the disease as an endogenous toxæmia, but Waller (1942) has brought evidence in favour of a virus origin. From the blood of acutely affected birds he has isolated a filtrable agent that grows readily on the chorio-allantoic membrane of the developing chick embryo. Susceptible chickens inoculated with infected membrane become depressed and cyanotic in 3–4 days. They do not die but, if killed after 4–5 days, they show subcutaneous œdema, generalized jaundice, hæmorrhages into the skeletal muscles, petechial hæmorrhages in other organs, congestion and swelling of the liver and kidneys, and acute catarrhal hæmorrhagic duodenitis. Fæces of experimentally infected birds are infective to other birds by the mouth. Intraperitoneal inoculation of susceptible chickens with a bacteria-free filtrate of infected fæces likewise reproduces the disease. The virus passes through a Chamberland L3 and a Seitz filter. Its relationship to the disease must await further inquiry.

Virus Disease of Owls

A virus disease affecting the great horned owl (*Bubo virginianus*), and transmissible experimentally to the same species and to the screech owl (*Otus asio*), has been recognized by Green and Shillinger (1936) in the United States. The disease is characterized by the formation of multiple abscesses in the liver, and, less constantly, in the spleen. Large intranuclear inclusion bodies occur in the hepatic cells. Nothing is known about other properties of the virus.

CHAPTER 89

FILTRABLE VIRUS DISEASES—*Continued*

E. GROUP CHARACTERIZED BY TUMOUR FORMATION

THE group of virus diseases characterized by tumour formation is of particular interest in affording a possible clue to the genesis of neoplasms. In this chapter we must confine ourselves to factual description; but those who are interested in the wider aspects of the subject would do well to refer to the far-reaching speculations of Andrewes (1939*b*) and of Rous (1943).

FOWL LEUCÆMIA

This is an infectious disease of the blood-forming organs, associated with atrophy of the bone marrow and changes in the viscera. The disease may be transmitted to normal fowls, but not to other birds, by intravenous inoculation with the citrated blood of infected fowls. According to Ellermann (1921), the virus can pass through a Berkefeld candle. Ellermann found that one strain of virus gave rise to three different types of leucæmia: (1) a myeloid type; (2) a lymphatic type; (3) an intravascular lymphoid type, characterized by intravascular deposits of lymphoid cells. An increase of virulence was noted during its passage through fowls, shown by a shortening of the interval between inoculation and death, from 15 to 20 weeks at the commencement, to 6 to 8 weeks at the end of the series of experiments. In spite, however, of the increased rate of killing, the infecting power of the virus, as judged by the proportion of successful inoculations, remained approximately constant at 20–40 per cent. Ellermann was unable to produce active immunity to the disease by subcutaneous inoculation of virulent material.

Furth (1932) found that infection could be transmitted by 0·000,001 ml. of cell-free plasma, and that the virus could withstand drying for at least 54 days. He also (1933) described a new transmissible strain of chicken leucosis which gave rise to (1) lymphomatosis with or without tumour formation, (2) myelocytomatosis with or without leucæmia, (3) endothelioma. The histology of the disease is beautifully illustrated in the monograph by Andersen and Bang (1928).

FOWL PARALYSIS

SYNONYMS: Lymphomatosis: neurolymphomatosis.

Though there is as yet no proof that this disease is caused by a virus, it may be well to make a brief mention of it here. The disease is common in both Europe and America. It affects particularly young birds, but may occur at any age. In many flocks it appears year after year. Some strains of birds appear to be more susceptible than others. The symptoms consist of asymmetrical paralysis

of the wings and legs, usually of slow onset, and more often spastic than flaccid. There is general loss of condition, and sometimes blindness. The disease is usually fatal, but recovery may occur. Pathologically, there is intense mononuclear cell infiltration of the nerves, especially the brachial and sciatic, leading to partial degeneration of the nerve fibres. The posterior root ganglia and, to a less extent, the spinal cord may be affected. Lymphomatous deposits, amounting at times to tumours, may be present in the viscera, especially the ovary. There is no leucæmia. The disease can be reproduced irregularly in normal birds by the intraperitoneal or intracerebral injection of unfiltered lymphomatous tissue. About 25 per cent. of the inoculated birds may develop symptoms, after an incubation period of 2–4 months, but the rest remain healthy. By inbreeding, a strain of fowls may be obtained that are highly susceptible to natural or experimental infection. Passage of the virus through these birds results in an increase in its virulence with the production of an acute disease accompanied by inflammatory lesions in the heart and liver, and later by lymphomata. The evidence suggests that fowl paralysis is a chronic form of a disease that is partly or wholly symptomless during the acute stage. Attempts to demonstrate a virus by culture on the chorio-allantoic membrane of the developing chick embryo have yielded inconclusive results (see Pappenheimer *et al.* 1929*a*, *b*, Galloway 1929, McGaughey and Downie 1930, Dalling and Warrack 1936, Blakemore 1939, 1940).

Rous Sarcoma of Chickens

Rous (1911, Rous *et al.* 1912, Rous and Murphy 1914) described three transplantable sarcomata of fowls. Tumour I was a spindle-celled sarcoma that metastatized freely and caused death in a month; Tumour VII was an osteochondrosarcoma; and Tumour XVIII was a spindle-celled sarcoma with blood sinuses into which growth occurred. Each of these three tumours could be transmitted to normal fowls by the inoculation of cell-free Berkefeld filtrates. Gye (1925), who worked with the Rous Tumour I, has recorded evidence from which he concludes that the active agent is a living filtrable virus, which can be cultivated anaerobically in tubes of Hartley's broth to which 17 per cent. of rabbit serum, 0·2 per cent. KCl, and a fragment of chick embryo have been added. He believes that the tumour-forming activity of this virus is dependent on the presence of another, non-living factor, which determines the type of cell which is infected, and hence the type of tumour which is produced. This second, auxiliary agent he calls the "specific factor." The evidence in favour of the dual nature of the active agent in tumour-filtrates consists in the differential action of aerobic incubation and of various chemical agents. In an extensive series of experiments Gye found that (*a*) primary "cultures" incubated aerobically at 37° C. for 3 days were inactive; (*b*) filtrates, obtained by passing the ground-up tumour through a mixture of paper pulp and sand, when treated with chloroform, were inactive; but that (*c*) the inactivated "cultures" and the chloroform-inactivated filtrates, when acting in combination, gave rise to typical tumours. He would regard the specific factor in the "cultures" as being destroyed by aerobic incubation, and the virus in the tumour filtrate as being destroyed by the chloroform. He would also extend the conclusions based on these results to malignant neoplasms in general. Gye's results have not yet been completely confirmed by other workers, and his hypothesis is still in the stage of discussion and experiment (Gye and Mueller 1929, Amies and Carr 1939).

During the past two decades fresh filtrable tumours of fowls and other birds have been described, and considerable interest has centred around their ætiology. McIntosh (1933) and McIntosh and Selbie (1939) have reported that tumours induced by tar may be transmitted to normal birds by cell-free filtrates; and Selbie and McIntosh (1939) have found that the filtrability of fowl tumours may be increased by such procedures as proteolytic digestion or freezing and thawing, which presumably act by liberation of virus from the cells in which it is growing. The demonstration by Ledingham and Gye (1935) of what appear to be elementary bodies in infective filtrates, and the immunological studies of Andrewes (1931, 1932, 1933, 1936, 1939*a*), suggest more and more strongly that viruses, not differing in any important respect from those known to give rise to ordinary infectious diseases, play an essential part in the causation of these tumours (see Andrewes 1934). The particle size of the Rous sarcoma virus has been determined by Elford and Andrewes (1935, 1936). By the gradocol membrane technique it appears to be 75–150 mμ in diameter, and by the centrifugation method 60–70 mμ.

Molluscum Contagiosum

This is a contagious skin disease of man characterized by the formation of small red masses, which later take on a warty appearance, undergo necrosis, and discharge caseous material. MacCallum (1892) described peculiar bodies in material taken from the disease, which he regarded as due to nucleolar extrusion. They were later described by Lipschütz (1907) as very small rounded bodies, about 0·25 μ in diameter, arranged singly or less often in pairs. They can be stained with Loeffler's flagellar stain or with Giemsa. These molluscum bodies were at one time considered to be parasites, but are now generally regarded as inclusion bodies (Goodpasture and King 1927). The disease is apparently caused by a filtrable virus, since positive inoculation experiments in man have been reported with Chamberland filtrates of the tumour (Juliusberg 1905).

Common Warts

Numerous workers have recorded evidence which suggests that common warts are infectious. Jadassohn (1896) found that they could be produced in human beings by experimental inoculation. More recently Wile and Kingery (1919), and Kingery (1921), in a small series of experiments, were able to produce warts by intracutaneous inoculation of human beings with a Berkefeld filtrate of a suspension of ground-up wart material. In one case the warts were carried over successfully for two generations. The incubation period varied from 4 weeks to 6 months. Venereal warts—*condyloma acuminatum*—are infective and are apparently caused by a virus (see Findlay 1930); occasionally they may become cancerous. Warts are not uncommon in animals. According to Findlay (1930), there is some evidence to suggest that they are species-specific. For example, dog warts failed to infect man, rabbits, mice, or guinea-pigs; and human warts were non-infective for dogs, rabbits, guinea-pigs, rats, or mice.

Infectious Myxomatosis of Rabbits

Sanarelli (1898) described an infectious myxoma indigenous to rabbits of South America. The disease can be conveyed by inoculation of filtered material. Tumour masses appear quickly at the site of inoculation, and later at various other points in the subcutaneous tissue, as well as in the lymph glands and spleen. The disease

is very malignant and kills rabbits in 7 to 15 days. Rivers (1926–27) finds that both epithelial and connective tissue are affected, the epithelial cells being destroyed, and certain of the connective-tissue cells undergoing proliferation. In the epidermal cells he describes small pink granular areas occupying the cytoplasm. They increase rapidly in size and form acidophilic masses often containing blue, round or rod-shaped, bodies. Lipschütz (1927), who has made similar observations, regards these round or rod-shaped bodies as micro-organisms.

The virus is widely distributed throughout the tissues, though most abundant in the swollen tissues and lymph glands. It is killed by heat at 50° C. in 15 minutes. It is quickly inactivated by a pH of less than 4·6. It withstands the action of glycerol for a year in the ice-chest. It is highly species-specific, and appears to be almost uniformly fatal for the domestic rabbit (see Rivers 1930, Findlay 1933, Hyde and Gardner 1933, Ledingham 1937). Relatively pure elementary body suspensions have been prepared by Rivers and Ward (1937). They have been shown to contain a soluble antigen, which may be demonstrated as a precipitinogen in the serum of infected animals. This antigen, which is a heat-labile protein, stimulates the production in rabbits of precipitins and agglutinins, but not of neutralizing antibodies (Rivers *et al.* 1939). By microscopical examination van Rooyen (1937*b*) estimates the elementary bodies to be about 0·31–0·36 μ in diameter, but other methods suggest a size of only 125–225 mμ (see Mueller 1941, Stanley 1943). The virus has been cultivated on the chorio-allantoic membrane of the developing chick embryo (Lush 1937, Hoffstadt *et al.* 1941). The relation of this virus to the virus of infectious fibromatosis of rabbits will be discussed below. A neurotropic strain of the myxoma virus has been developed by Hurst (1937) as the result of serial passage through the brain of rabbits. This strain does not prove fatal on intracutaneous inoculation, and the histological picture to which it gives rise differs from that of the parent strain. Animals inoculated with the neuromyxoma strain are protected against subsequent inoculation with the myxoma-producing virus.

Infectious Fibromatosis of Rabbits

This disease, which was first observed by Shope (1932) (see also Shope 1936*a*) in cotton-tail rabbits, is of the nature of a filtrable fibroma, which occurs in the subcutaneous tissue. It can be transmitted by filtrates of the tumour suspension to wild and domestic rabbits, but not to other animals. Cytoplasmic inclusions are demonstrable in the cells. The condition is non-fatal, and undergoes spontaneous retrogression. The virus is resistant to glycerol, and is apparently different from that causing infectious myxomatosis. A very remarkable mutant strain has been derived from it which gives rise to acute inflammatory lesions instead of the usual proliferative changes (Andrewes 1936, Shope 1936*b*, Andrewes and Shope 1936, Editorial 1936). Rabbits that have been inoculated intramuscularly with tar respond in an abnormal way to the infectious fibroma virus. Regression of the lesions produced by intradermal or subcutaneous inoculation of virus is much delayed, continuous tumour growth is not uncommon, and transformation to a fibrosarcoma may apparently occur (Ahlström and Andrewes 1938, Andrewes and Ahlström 1938). The diameter of the fibroma virus has been estimated by the gradocol membrane technique to be 125–175 mμ, and by the centrifugation technique 126–141 mμ (Schlesinger and Andrewes 1937).

The remarkable relationship of the infectious fibroma virus to the infectious

myxoma virus of rabbits was first pointed out by Shope (1932), who found that animals which had recovered from infection with the fibroma virus enjoyed a considerable measure of immunity to the myxoma virus. Conversely, rabbits that recover naturally from myxomatosis—and these are very few—are immune to the fibroma virus (Ledingham 1937). The mechanism of this cross-immunity is not clear, but there is little doubt that the two viruses agree closely in antigenic structure. Berry and Dedrick (1936) and Berry (1940) found that, if a mixture of myxoma virus, which had been inactivated by heating at 60°–80° C. for 30 minutes, and of active fibroma virus was injected into a rabbit, myxomatosis resulted. This observation has been confirmed by several workers (for references see Gardner and Hyde 1942), but its interpretation is at present in doubt. Whether the fibroma virus undergoes transformation into the myxoma virus, or whether the apparently killed myxoma virus is activated by the living fibroma virus, the available evidence does not permit us to say.

Infectious Papillomatosis of Rabbits

This disease has been described by Shope and Hurst (1933). It affects cottontail rabbits, and is characterized by the presence of warty or horn-like protuberances on various parts of the body. Infection can be transmitted in series through cottontail rabbits. Only a proportion, however, of these animals are susceptible, and in more than half of those animals in which papillomata do develop retrogression of the growths occurs sooner or later. Malignant change is rare. The domestic rabbit, on the other hand, is highly susceptible. Not only do papillomata develop readily, but a considerable proportion of them undergo carcinogenic transformation (Rous *et al.* 1936). According to Shope (1937), papillomatosis of the domestic rabbit cannot usually be transmitted by passage, nor is it easy to demonstrate the presence of virus in the growths (see also Kidd 1938). The papilloma virus can infect epidermal tumours induced by tar, and may bring about in them an abrupt change into carcinomata; direct demonstration of the virus in the carcinomatous tumour has so far failed, but its presence can be shown by serological methods (Rous 1943). An even more rapid method of bringing about the carcinomatous state is to apply methylcholanthrene and tar to virus-induced papillomata; the chemical agents appear to act, not as ordinary stimulants of cell proliferation, but as specific carcinogens affecting the virus (Rous and Friedewald 1944).

The papilloma virus is filtrable through a Berkefeld candle, resists the action of glycerol, and is killed by exposure to 70° C. but not 67° C. for 30 minutes. By the gradocol membrane technique its size has been computed as 23–35 mμ, and by the centrifugation technique as 32–50 mμ (Schlesinger and Andrewes 1937). Studies by the electron microscope suggest that the particles are spherical and have a mean diameter of about 44 mμ (Sharp *et al.* 1942). Rabbits with experimentally produced papillomata are partly or completely immune to re-infection, and their serum has neutralizing and complement-fixing properties (see Kidd 1938). Artificial immunization by intraperitoneal injection of glycerolated or non-infective virus has been described (Shope 1937).

Oral Papillomatosis of Rabbits

Parsons and Kidd (1943) have met with a disease among domestic rabbits in New York City characterized by the occurrence of small, usually multiple, benign

papillomata on the under side of the tongue. They persist often for several months but, unlike the Shope papilloma, do not become malignant. The disease can be reproduced in rabbits and horses, but not in other animals, by local inoculation of a tumour suspension. The resulting lesions are strictly confined to the oral mucosa—a site which is not affected by the Shope virus. Infection does not spread readily by contact. It is probably transferred from the mother to the young by suckling, and remains latent till it is activated by trauma or, experimentally, by tar. The virus passes through a Berkefeld N candle. In water-clear suspensions it is destroyed by exposure to 75° C. but not 65° C. for 30 minutes. In 50 per cent. glycerol Locke solution in the ice-chest it survives for 1–2 years at least.

Hodgkin's Disease

Little is known of the ætiology of this fatal disease, in which characteristic histological changes are usually found in the enlarged lymph glands and lymphoid deposits. Gordon (1933, 1934, 1936) has described the reproduction of meningo-encephalitis in rabbits by the intracerebral inoculation of autolysed gland suspensions. Elementary bodies are said to be distinguishable in human material and in impression preparations of infected rabbit's brain. Gordon's test is said to be of diagnostic value in about 75 per cent. of cases of Hodgkin's disease (van Rooyen 1934, 1937*a*). The encephalitogenic agent is said to pass through British Berkefeld and Seitz EK filters; to be inactivated by exposure to a temperature of 80° C. for 30 minutes; to withstand 0·5 per cent. phenol at 37° C. for probably a week or longer; and to be neutralized by the serum of a rabbit that has recovered from the infection (van Rooyen 1934). In considering the nature of this agent it is interesting to note that Friedemann and Elkeles (1933) reported the production of encephalitic symptoms in rabbits following intracerebral injection with bone marrow from cases of acute leucæmia and pernicious anæmia. Friedemann (1934) demonstrated the presence of a similar property in normal human leucocytes bone marrow, and splenic tissue. MacKenzie and van Rooyen (1935) confirmed these findings, and concluded that the agent present in certain normal tissues, is indistinguishable from that present in lymphadenomatous glands. What the nature of this agent is, it is difficult to say. Its resistance to heat, alcohol, and ether render it unlikely that it is a virus. Moreover, the inability to transmit the agent from one rabbit to another, and the susceptibility to re-inoculation of rabbits that recover, are points against its virus nature (van Rooyen 1934). Van Rooyen (1937*a*) sums up by concluding that Hodgkin's disease is essentially a neoplastic process affecting lymphatic gland tissues. Whether or not a virus is concerned in the neoplastic activity must, for the present, remain an open question.

It may be noted that Petzetakis (1936, 1937*a*, *b*) described the isolation of a so-called neurolymphophilic virus from a patient suffering from chronic suppurative lymphadenitis. Inoculated intraperitoneally into guinea-pigs, it gave rise to hypertrophy of the lymph nodes, Peyer's patches, and spleen, and inoculated intracerebrally to a fatal meningo-encephalitis. Rabbits and spermophiles were also found to be susceptible. Petzetakis' findings were not confirmed by Béquignon and Reinié (1937).

It is of interest that organisms of the *Brucella* group have been isolated from the lymph nodes of patients suffering from Hodgkin's disease (Poston and Parsons 1940); but there is no reason to suppose that they are causally related to this disease.

CHAPTER 90

THE NORMAL FLORA OF THE HUMAN BODY

THE normal flora of the human and animal body has received relatively little attention from bacteriologists in the past, and it is only within recent years that any serious attempt has been made to study it in detail. Before describing the organisms met with in different parts of the body, it is necessary to realize certain general principles regulating their distribution. Firstly, our conception of the normal flora depends very largely on the technique that is employed. A survey based upon examination of stained smears frequently gives results quite different from a survey based on cultural examination. And the results obtained with one culture medium may differ widely from those obtained with another. The main reason for this difference is that every culture medium is more or less selective in its action; it encourages the growth of some organisms and hinders or entirely prevents the growth of others. For example, very different pictures of the intestinal flora will be obtained on agar plates and on MacConkey plates; on the latter medium the bile-salts will inhibit the growth of nearly all organisms except the Gram-negative coliform bacilli, whereas on agar numerous cocci, Gram-positive bacilli, and other organisms will develop as well. Similarly, very different pictures of the nasopharyngeal flora will be obtained if swabs from this region are plated (*a*) on ordinary agar, (*b*) on blood agar, and (*c*) on a selective medium such as Fildes' agar. The method of incubation is of great importance; cultures incubated anaerobically will reveal a very different flora from those incubated aerobically. Incubation at 22° C. is unfavourable to the growth of many pathogenic species.

Having realized the importance of the technique employed, it is necessary to understand that the term "normal" flora may be misleading. It is possible to give a description of the intestinal or nasopharyngeal flora which will apply to the great majority of adult persons living under particular environmental conditions; but this description may not be applicable, or may apply only in part, to another community, consuming a different diet, or exposed to a different climate. There are certain bacterial species which, so far as our information goes, are constantly present in particular situations. Thus, *Bact. coli* appears to be a normal intestinal parasite of man in all parts of the inhabited globe; *Str. viridans* is, so far as we know, always present in the nasopharynx; and *Staph. albus* seems always to be present on the normal skin. In addition to such constant constituents of the human bacterial flora, there are, however, very many species whose range is limited in space and time. Many of these species are potential pathogens, such, for instance, as the pneumococcus, the meningococcus, the influenza bacillus, and hæmolytic streptococci, among the nasopharyngeal flora; but it is probable that many non-pathogenic species show a similarly localized

distribution. If our knowledge were more extensive than it is, we should probably be able to describe a basal flora, characteristic of mankind under all conditions; a supplementary flora, varying in frequency, but ranging widely as normal parasites of man; and various species showing a restricted range or a temporary prevalence, conditioned by localized or transient environmental factors. This aspect of bacterial ecology has, however, received relatively little attention, except with regard to the incidence of a few important pathogenic species. If we include, among the normal flora of a particular region of the body, all those bacterial species which may be isolated from any considerable sample of apparently healthy persons, we must note that this flora varies widely, from time to time, and from place to place.

The nature of the intestinal flora, for example, depends on a number of factors, such as diet, gastric acidity, degree of peristalsis, external temperature, and so on. The predominant flora on a herbivorous differs from that on a carnivorous diet; in the upper part of the small intestine it is more copious in persons with gastric hypoacidity than in normal persons. Again, the flora of the nasopharynx is constantly changing both in the same individual and in the same community. At one time, pneumococci and Pfeiffer's bacilli may be present in large numbers in apparently healthy persons, whereas at another time they may be far less frequent. It must be realized, therefore, that, in the account which follows, we can make no attempt to give a complete description of the organisms that may be found in different parts of the body, or to indicate more than roughly their frequency and relative proportions.

The species found in the regions of the body which are normally colonized by bacteria include those generally accepted as pathogens, those generally accepted as saprophytes, and many that are intermediate. We know very little of the nature of the association between the bacterium and the healthy host tissue in any of these three cases. We may regard all typical members of a pathogenic species as virulent, and postulate a high level of immunity, perhaps specific, in order to explain the prevalence of the organism in the normal flora; or we may postulate a wide variation of virulence in the species, and assume a lesser virulence for the strains found in healthy tissue. For example, as we saw in Chapter 74, the "carrier" types of pneumococci appear to invade the lung tissue of carriers only when the host is subjected to debilitating influences, and the "infective" types may be carried by healthy people who have acquired an immunity to them (see, for example, Finland, Brown and Barnes 1940); and there are indications (Chapter 54) that the normal fusiform bacilli of the mouth may initiate ulcerative lesions in the mouth of vitamin-deficient animals. But except where there is an abnormally high specific antibody response to a species that occurs in the flora of normal tissues, any explanation in terms of a balance between the virulence of the "pathogen" and the resistance of the host is little more than a re-description of the observed state of affairs, though it serves to emphasize that the coexistence of bacterial with host cells is the result of an equilibrium between two sets of factors, and not merely a mutual indifference to each other's presence. And by analogy with a large number of instances of biological associations variously described as parasitism, saprophytism, commensalism, symbiosis, etc., we may expect that the associations of saprophytes and healthy tissue cells are equally dynamic.

Moreover, equilibria exist not only between host and "normal" flora, but

between the different species within the flora; and the association of various bacterial species on a given surface of the body is relevant to any discussion of infection. It cannot be too strongly emphasized that none of those regions of the body, to which bacteria can gain entrance by the normal portals, provides a virgin soil in which any new-comer may flourish. It is just as impossible to ensure the proliferation of a particular bacterial species by introducing it into the mouth, as it is to ensure a crop of a particular plant by scattering seeds in a field already occupied by a pre-existing plant-association. The new-comer will have little chance of survival, unless it is adapted to occupy some definite place in its new environment. It is fairly certain that those pathogenic bacteria which spread readily from host to host owe their capacities in this direction to their ability to colonize on skin or mucous surfaces, or to escape from the superficial environment to the underlying tissues. This question, in relation to the upper part of the respiratory and alimentary tracts, has been studied in some detail by Bloomfield and his colleagues (Bloomfield 1919, 1921, 1922*a*, *b*, *c*, *d*, *e*, Bloomfield and Felty 1923*a*, *b*, *c*, Felty and Bloomfield 1923).

Normal Flora of the Alimentary Tract.

The bacteria present in the *mouth* are subject to great variation both in number and in kind. Even the relatively clean and healthy mouth contains a considerable amount of detritus and other organic matter derived from particles of food, desquamated epithelium, pharyngeal mucus, and other sources; these provide nutriment for a diverse flora which is of necessity undergoing frequent change. Moreover, inflammatory processes of the teeth and gums are often present, favouring the growth of pyogenic bacteria. The saliva has apparently only a slight bactericidal effect, and it is perhaps surprising that, with so much organic matter in the mouth and so many organisms to grow in it, septic infections are not more common. There are probably three main reasons for this: firstly, the saliva, though not conspicuously bactericidal, by its constant secretion tends to flush the mucous surfaces of the mouth, and wash off many of the adherent organisms, which, when swallowed, are rapidly killed by the gastric juice; secondly, the mucosa of the mouth has a remarkably good blood supply, and it is a general rule that the better the blood supply of a tissue, the less liable it is to invasion by pyogenic bacteria; thirdly, as Bloomfield (1922*c*) has shown, there is a highly efficient mechanism, apparently dependent on suction currents, by which any bacteria introduced into the mouth are drawn directly backwards towards the œsophagus, avoiding the tonsils and posterior wall of the pharynx. Of the great number of different organisms found in the mouth and saliva, among the commonest are (1) Micrococci, some of which form pigment and some of which do not; the non-pigment-forming micrococci include some that are anaerobic (Ozaki 1915); (2) Staphylococci, especially a white pigmented type; (3) Streptococci, either of the α-hæmolytic type, such as *Str. viridans*, or of the indifferent type; (4) Gram-positive bacilli, often arranged in chains, and belonging to the group of aciduric bacilli, or of aerobic spore-bearing bacilli; (5) Gram-negative bacilli, including organisms of the coliform and *Proteus* groups; (6) Spirochætes; these are almost invariably present between the gums and the teeth; several types have been described, such as *Treponema buccalis*, *Treponema dentium*, *Treponema intermedium* (Dobell 1912), *Treponema microdentium*, *Treponema macrodentium* (Noguchi 1912), Vincent's spirillum, and Miller's

spirillum. Organisms of the *Actinomyces* and *Fusiformis* groups are not uncommon (see Brooke 1938, Rosebury, Epps and Clark 1944, and Chapter 18).

The *intestinal flora* of the breast-fed *infant* is relatively simple, consisting largely of *Lactobacillus bifidus*; this bacillus in the early weeks of life may constitute 99 per cent. of the total organisms in the fæces (Cruickshank 1925). There are in addition a few enterococci and Gram-negative coliform bacilli (Tissier and Dreyfus 1925). Snyder (1940), who followed the changes in fæcal flora of infants from birth until some weeks after weaning, confirmed the predominance of *L. bifidus* in breast-fed infants, but found it also in 25 per cent. of the weaned infants. Coliforms and enterococci were also present in the breast-fed, but their frequency increased with weaning, and at the same time clostridia and members of the *Fusiformis* group became characteristic features of the fæcal flora. It is of interest that *Staph. aureus* was found in about 8 per cent. of the fæces at all stages—a frequency which may reflect the readiness with which the infant's nose is colonized by this organism soon after birth (see nasal flora, below).

The intestinal flora of bottle-fed infants is not so simple. *L. bifidus* is uncommon; on the other hand, another member of the aciduric group of bacteria —*Lactobacillus acidophilus*—is usually present in large numbers (Tissier 1900). Different types of coliform bacilli, enterococci, Gram-positive aerobic spore-bearing bacilli and anaerobic bacilli, occur more or less abundantly. Two moderately pathogenic clostridia, *Cl. capitovale* and *Cl. difficile*, were first discovered in the stools of normal infants (Snyder and Hall 1935, Hall and O'Toole 1935, Snyder 1937).

In the *adult*, numerous workers have found that the empty *stomach* is generally sterile. Immediately after a meal it contains numerous organisms, which have been ingested with the food; but these, with the exception of acid-resistant vegetative bacilli and sporing bacteria, appear to be killed off rapidly. If, however, the motility of the stomach is excessive, or the acidity is below normal, this sterilizing effect of the gastric juice is probably incomplete. Thus in cases of gastric disease—particularly of carcinoma—sarcinæ, saprophytic bacilli, and other organisms may actually multiply in the stomach (Goodsir 1842, Oppler 1895). In the healthy adult there appear to be very few organisms in the duodenum and upper jejunum. Below this level they increase, and reach their maximum numbers in the large intestine.

The organisms present in the upper part of the *small intestine* appear to consist chiefly of enterococci. In the lower part numerous other organisms are found, and in much larger numbers; amongst these are Gram-negative coliform bacilli, staphylococci, various gelatin-liquefying organisms, sarcinæ, yeasts, and sometimes aciduric bacilli (Niszle 1928). In the *large intestine* the flora is even more complex and numerous. The following organisms are commonly found: coliform bacilli of different types, enterococci, staphylococci of both the *aureus* and *albus* varieties, anaerobic spore-bearing organisms such as *Cl. welchii* and *Cl. putrificum*, aciduric bacteria including *L. acidophilus* and *L. brevis*, thermophilic bacteria, spirochætes (Werner 1909), and yeasts; less frequent are *Proteus* bacilli, *Ps. pyocyanea*, organisms of the Friedländer group, and aerobic spore-bearers such as *B. subtilis* and *B. mesentericus*. Hæmolytic streptococci of Groups D, B, C, F and G are occasionally found, Group D being the commonest (Smith and Sherman 1938). The proportion of anaerobic to aerobic bacilli in the intestine has probably been underestimated by most workers. Anaerobic organisms appear, in fact, to be very

common in the fæces. Eggerth and Gagnon (1933) and Eggerth (1935), examining 65 specimens of normal stools, found that in nearly all of them the predominating organisms were obligate non-sporing anaerobes. The exact classification of these organisms was open to doubt; some were Gram-positive and some Gram-negative. It is probable that they belonged partly to the *Fusiformis* and partly to the *Lactobacillus* groups. These findings have been confirmed by Weiss and Rettger (1937), and Misra (1938). It may be noted that bacteria are said to make up 1/4–1/3 by weight of the fæces; the greater part of them seem to be dead.

It is of interest to consider why the upper part of the small intestine contains so few living bacteria. It appears that the "*auto-disinfecting mechanism*" of the duodenum—as described by Arnold and Brody (1926)—is dependent on the acid derived from the stomach. In normal persons the H-ion concentration of the duodenum and upper jejunum is about pH 5·5–6·3. The gastric contents entering the duodenum are saturated to their full buffer capacity, usually with an excess of free acid. The free acid is quickly neutralized by the bile, and by the pancreatic and intestinal juices; the acid-buffered material is neutralized more slowly, and is chiefly responsible for maintaining the acidity of the contents of the upper part of the small intestine. In the presence of this degree of acidity few organisms are able to multiply; but if, from gastric hypoacidity, the reaction of the duodenum becomes neutral or slightly alkaline, a rich bacterial flora develops. This can be imitated experimentally in dogs by injecting alkaline buffered solutions into the duodenum, by feeding with alkaline salts, or by raising the external temperature (Arnold and Brody 1926).

Dack and Woolpert (1932), obtained rather different results with monkeys. They found that *Chromo. prodigiosum* introduced by fistulæ into different parts of the intestine disappeared just as rapidly as when given by the mouth and made to pass through the stomach. Estimations of pH at different levels showed that the stomach contents had a pH approximately of 4–5, the duodenal of 6–7, the jejunal of 6–7·5, the ileal of 6–7, the cæcal of 5–7, and the descending colon of 5·5–7. In experiments *in vitro* a pH of about 4 was required to bring about a rapid reduction in the number of these organisms. This pH was met with only in the stomach. If, therefore, bacterial destruction occurs as rapidly in the intestine of the monkey as in the stomach, it is clear that acidity cannot be solely responsible. Bergeim has described two antibacterial mechanisms in the cæcal contents of rats and man, one dependent on volatile fatty acids—formic, acetic and butyric—the other on H_2S. At the pH of the cæcal contents, butyrate from a high butter fat diet was found to act slightly on *L. acidophilus* or yeasts, and more strongly on *Bact. coli*, *Proteus vulgaris*, and salmonellæ. If rats on this diet were given $CaCO_3$ to raise the pH of the intestinal contents, the proportion of *Bact. coli* in the fæces increased. In concentrations that occurred naturally in the cæcum of rats and man, H_2S killed yeasts, and inhibited *Bact. coli* to some extent, but hardly affected *L. acidophilus* or the enterococcus (Bergeim 1940, Bergeim *et al.* 1941).

Provisionally we may conclude that in healthy persons the majority of the organisms ingested in the food and swallowed with the saliva are destroyed in the stomach by the gastric juice. The few surviving bacteria that pass through unharmed find the conditions in the duodenum and upper jejunum too acid to allow them to multiply. With their further passage down the intestine, they encounter progressively more alkaline conditions, and are able to proliferate accordingly (see Chapter 45).

The variations of intestinal flora within mammalian species may be very great. For example, the normal flora of the guinea-pig intestine was found by Crecelius and Rettger

(1943) to be relatively simple; a lactobacillus resembling *L. acidophilus* constituted approximately 80 per cent. of the total cultivable flora, the remainder being accounted for mainly by soil and air bacteria, yeasts, and an anaerobic sarcina. Coliform organisms and enterococci were seldom present. Again, according to Porter and Rettger (1940) the flora of the white rat on a normal mixed diet consists mainly of lactobacilli and coliform organisms; very few cocci are found. Lactobacilli were common in the stomach, where little else but yeasts were demonstrable. The bacterial content of the duodenum and jejunum was low, and no lactobacilli were present. Coliforms and lactobacilli were present in the lower parts of the small intestine, and abundant in the large intestine, where spore-bearing anaerobes also appeared. The lactobacilli were generally reduced by meat, to some extent by other types of high protein diet, and by several days' starvation. Except in the lower gut, it may be noted, there was little correlation between the pH of the gut contents and the predominating flora.

Origin of the Alimentary Flora.—Witkowski (1935), investigating the origin of the mouth flora, found that organisms could be demonstrated in the mouths of 49 out of 50 infants shortly after birth. These comprised mainly *Staph. albus*, coliform bacilli, Döderlein's bacillus, and streptococci. Examination of vaginal swabs from the mothers showed that these organisms were all present in the vagina in proportions corresponding fairly closely to those in the infant's mouth. It seems probable, therefore, that the initial flora of the infant's mouth is derived from the vagina of the mother. By 2–5 days after birth other organisms had appeared consisting, in decreasing order of frequency, of pneumococci, hæmolytic staphylococci, various types of streptococci, Friedländer bacilli, corynebacteria, sarcinæ, and Gram-negative cocci. Comparison of these findings with the mouth flora of the mother showed a considerable degree of correspondence, suggesting that the infant had derived these additional organisms from the nasopharyngeal tract of its mother and other persons in its environment.

The intestine at birth is either sterile, or contains a few bacteria; infection rapidly occurs, partly from above and partly from below.

Schild (1895) found that the anus became contaminated with organisms from the air, bath-water, and other objects with which it came into contact. Organisms could be demonstrated in the meconium sometimes within 4 hours of birth, and usually within 10–17 hours. When the anus was disinfected and covered with a sterile towel, the meconium remained free from organisms for 20 hours—by which time infection had occurred from the food.

The sterility of the meconium observed by Schild was confirmed by several observers (see, for example, Passini 1932), though a number of others have cultivated bacteria from 10–38 per cent. of samples examined soon after birth, indicating the possibility of small degrees of prenatal contamination of the fœtus (Hymanson and Hertz 1917, Burrage 1927, Hall and O'Toole 1934, Snyder 1936).

The Importance of Micro-organisms in the Intestine.

It was at one time widely believed that the presence of bacteria in the intestine was essential for the life of the host, that they assisted in the digestive processes, and that without them much of the food taken in would be passed out of the body again in an unassimilable condition. This belief arose as a very natural deduction from Pasteur's work on the microbial nature of fermentation. It was largely owing to Metchnikoff, who came to regard the intestinal flora with hostile suspicion, that the possibility of maintaining life with a sterile intestinal tract began to be considered seriously. Numerous workers had already devoted themselves

to the realization of this possibility; notable amongst them was Schottelius (1899, 1902, 1908), who spent several years endeavouring to rear chicks under sterile conditions, and failed. Nuttall and Thierfelder (1895–96) met with some success; they removed an embryo guinea-pig by Cæsarean section, and maintained it uncontaminated for 8 days, after which the experiment had to be given up owing to technical difficulties. They convinced themselves, however, that bacteria in the intestinal canal are not necessary for life—so long, at least, as an animal diet is provided. It was Cohendy (1912) who finally succeeded in showing that prolonged life was possible under such conditions. By means of a specially constructed apparatus, he reared chicks under completely sterile conditions for from 12 to 40 days, and found that they developed and grew as well as control non-sterile chicks kept in a similar apparatus. The only difference noted was that the food of the sterile chicks was less perfectly digested than that of the control chicks; but the sterile chicks made up for this by eating more. Cohendy concludes that life is possible with a sterile intestinal tract, but that the intestinal bacteria are probably of use in assisting digestion. How far the second part of this conclusion is applicable to man, whose diet contains very much less indigestible material than that of the chick, it is impossible to say. Cohendy states that his sterile chicks survived exposure to moisture, hunger, and thirst for several days; whereas normal chicks proved extremely susceptible to such conditions. His explanation is that, as the chicks were free from all micro-organisms, they could not, however low their resistance might be, succumb to infection from the intestine or other parts of the body.

It is easy to pass from the conclusion that bacteria are unnecessary for the human organism to the conclusion that they are actively harmful. This is a transition that has been unjustifiably made. We have no space to discuss the question of *intestinal toxæmia*. The conception that numerous cases of ill-health and of actual well-defined disease processes are due to the absorption, from the intestine, of toxic products elaborated by proteolytic micro-organisms is a plausible one, but one that rests largely on unproven assumptions. It is the almost complete lack of experimental evidence that renders the discussion of this subject so fruitless at the present time (see Discussion 1913, Dudgeon 1926).

The earliest method attempted in efforts to prevent the possible absorption of toxins from the intestine, was the replacement of the putrefactive flora—anaerobic spore-bearers such as *Cl. sporogenes*, *Cl. putrificum*, and *Cl. histolyticum*; aerobic spore-bearers such as *B. mesentericus*; and organisms such as *Proteus vulgaris* and *Ps. pyocyanea*—by an organism of the aciduric group known as *Lactobacillus bulgaricus*. These attempts failed completely. It has since been found impossible to implant this bacillus in the normal intestine; the conditions for its growth are unfavourable. Recent experimental work has shown that, in order to encourage the growth of a given type of organism in the intestine, it does not suffice to administer such an organism by the mouth, but that it is also essential to give by the mouth a sufficient quantity of a selective food material to enable it to flourish at the expense of other organisms. The replacement of a proteolytic by a saccharolytic flora—aciduric bacilli, *Cl. welchii*, and the enterococcus—can be largely accomplished by feeding on a high carbohydrate diet. In rats it has been found that by giving large quantities of lactose or dextrin in the diet, the intestinal flora can be so changed that it contains 90 per cent. or more of aciduric bacilli (Rettger and Cheplin 1921, Cannon and McNease

1923, Cruickshank 1928). These two carbohydrates are absorbed very slowly, and consequently pass into the large intestine. They are there acted upon by the aciduric bacilli—notably *L. acidophilus*—with the formation of a large amount of lactic acid ; the presence of this acid is unfavourable to the persistence of the proteolytic bacteria. Without the supply of lactose, dextrin or milk the aciduric bacilli cannot be successfully implanted in the intestine, even though pure cultures are given in large quantity daily. In infants 12 per cent. of lactose must be added to whole cow's milk or to lactic acid milk in order to convert the mixed intestinal flora into a lactobacillary flora similar to that found in the stools of breast-fed babies (Gerstley, Howell, and Nagel 1932). This is not the place to discuss the value of changing the intestinal flora in the treatment of constipation and other disorders, but we will refer our readers to the monograph by Rettger and his colleagues (1935). (See also Sanborn 1931*a*, *b*, Kopeloff *et al.* 1932, Weinstein *et al.* 1938.)

In the normal human adult, living on a mixed dietary, no sharp division into proteolytic and saccharolytic bacteria in the fæces can be made. As Dudgeon (1926) points out, the term " proteolytic " is often used without any definite understanding of its connotation. Many workers include *Bact. coli* in the proteolytic flora, which is quite inadmissible ; *Proteus vulgaris*, and *Ps. pyocyanea*, both of which are proteolytic, are uncommon in the fæces ; anaerobic bacteria, such as *Cl. sporogenes* and *Cl. putrificum*, are demonstrable in only a small proportion of samples ; while the clostridium that is most commonly present, *Cl. welchii*, has only weakly proteolytic powers. Dudgeon lays emphasis on the importance of diet in regulating the intestinal flora (see also Torrey 1930) ; he would regard, in fact, the normal flora as being determined largely by the number of organisms ingested, and by the favouring or inhibitory effect of various articles in the dietary on the multiplication of one or more types of bacterium already present in the intestine. In the practical examination of the intestinal flora, he considers it essential for the patient's diet to be rigidly controlled, and for several methods of investigation—microscopical observation of films stained by different methods, and aerobic and anaerobic cultivation in different media—to be employed.

Intestinal Bacteria as Food-stuffs. Although the limited experiments with animals reared in a sterile environment indicate that bacteria are not necessary for the human organism, there is growing evidence that in certain circumstances the intestinal bacteria may contribute to the well-being of the host.

Thus, on diets deficient in members of the Vitamin B complex, an increase in these vitamins, in some cases up to 70-fold, has been demonstrated in the rumen of cows and ewes (Bechdel *et al.* 1928, McElroy and Goss 1939, Wegner *et al.* 1941). Bechdel found a flavobacterium, constituting 90 per cent. of the flora of the rumen, which proved to be a potent source of the B complex when grown in a vitamin-free medium. Again, in a number of heifers fed with urea and carbohydrate, protein was synthesized, apparently by various iodophilic bacteria, in amounts sufficient to satisfy a substantial part of the protein requirements of the animal (Pearson and Smith 1943, Smith and Baker 1944).

The synthesis of vitamins in substantial amounts is not a peculiarity of bacteria in the rumen of herbivores. *In vitro*, the intestinal bacteria of man—for instance *Bact. coli* and *Bact. aerogenes*—synthesize biotin, riboflavin, thiamin, nicotinic acid (Burkholder and McVeigh 1942) and Vitamin K (Dam *et al.* 1941). Synthesis *in vivo* has been demonstrated in two ways, namely by noting the continued excretion of a vitamin in an animal upon a vitamin-free diet—depletion of the body reserves being excluded as a possible source ; and by the induction of avitaminosis by partial sterilization of the intestinal contents with sulphaguanidine or succinyl sulphathiazole, followed by the cure of the avitaminosis during drug-therapy by giving adequate doses of the appropriate vitamin.

The sulphonamide is said to act by reducing the number of vitamin-synthesizing bacteria, or (Gant *et al.* 1943) by reducing their ability for synthesis.

The results so far obtained by these methods strongly suggest that in the alimentary canal of the rat, Vitamin K (Black *et al.* 1942), biotin, folic acid (Nielsen and Elvehjem 1942), the B-complex, Vitamin E (Daft and Sebrell 1942), and possibly certain essential amino-acids (Martin 1944) are synthesized by bacteria and used by the host. In man, a similar dependence upon intestinally-synthesized thiamin (Najjar and Holt 1943; but see Alexander and Landwehr 1945), riboflavin (Najjar *et al.* 1944) and nicotinic acid (Ellinger, Coulson and Benesch 1944) has been demonstrated. It is not yet known whether the intestinal organisms need minimal quantities of the vitamins in the diet to initiate the synthesis. Nor is it known whether the vitamins so manufactured are necessarily absorbed as such; but we may note the suggestion of Petri, Norgaard and Bandier (1940) that the synthesis of co-enzymes I and II from nicotinic acid, of cocarboxylase from thiamin and of riboflavin from flavoproteins, takes place in the stomach.

As we have seen in Chapter 54, the fact that a substantial amount of the vitamin or food requirements of an animal may be satisfied by the bacteria in its alimentary canal affects the interpretation of a good deal of recorded work on experimental variations of diet. It also throws light on the association of deficiency states with diarrhœal syndromes, and with prolonged therapy of intestinal infections with drugs like sulphaguanidine and succinyl sulphathiazole.

Intestinal bacteria may also destroy essential food-stuffs. Thus, in the absence of a more readily fermented carbohydrate, *Bact. coli* and a number of other intestinal species will decompose Vitamin C in media containing organic nitrogen. It is not known to what extent dietary Vitamin C is destroyed in the alimentary canal, but the hypothesis of its decomposition by bacteria is in accord with the observation that certain scorbutic patients respond to injected, but not to oral, Vitamin C (Young 1942, Young and James 1942, Young and Rettger 1943). Again, nicotinic acid may be utilized as the sole source of nitrogen by organisms of the *Pseudomonas* group and by certain chromobacteria, though in the absence of nicotinic acid, these organisms synthesize the vitamin (Koser and Baird 1944; see also Benesch 1945). The production of a vitamin by the intestinal flora will clearly be determined by a multiplicity of factors, of which the presence of vitamin-producing and vitamin-destroying bacteria is only one; and the determination of these factors presents an exceedingly complex problem in bacterial ecology.

The Normal Flora of the Respiratory Tract.

For our present purpose we may divide the respiratory tract into three sections: an upper part, including the anterior and posterior nares and the nasopharynx; an intermediate zone, common to the respiratory and alimentary tracts, including the oropharynx and the tonsils; and a lower part, including the larynx, trachea, bronchi and lungs.

The bacterial flora of the nasal passages differs in several respects from that of the nasopharynx. It is less copious: if swabs are taken from the nose and nasopharynx of a sample of normal persons, and plated on some suitable medium, the nasal swabs will give the lower colony counts, and the differences observed are often striking. Qualitatively, diphtheroid bacilli and staphylococci—both *Staph. aureus* and *albus*—are far more frequent in the nose than in the nasopharynx, while *Str. viridans*, indifferent streptococci, and Gram-negative cocci of the *N. pharyngis* type, are far less frequent. These non-hæmolytic streptococci and Gram-negative cocci appear to constitute the basal normal flora of the naso-

pharynx in most communities, so far as this is revealed by the usual methods of cultivation; and it would seem that the flora of the oropharynx is composed mainly of the same species (Neumann 1902, Shibley *et al.* 1926, Noble *et al.* 1928, personal observations).

It would appear (Calamida and Bertarelli 1902) that the accessory nasal sinuses are normally sterile. According to Thompson and Hewlett (1896), the trachea and bronchi contain few, if any, bacteria. It is, of course, clear that a certain number of bacteria must be drawn through the larynx with the inspired air; but it would seem that the highly efficient filter provided by the tortuous nasal passages removes the great majority of the bacteria entering the nose. Those which penetrate beyond the vocal cords are promptly removed; in part perhaps by being swept upwards again by the cilia of the lining epithelium; in part by being caught up in the mucous secretion, and subsequently removed by expectoration; in part by removal, *via* the lymphatics, to the regional lymphatic glands. In any case it would appear that, in healthy persons, and under normal conditions, there is no permanent bacterial colonization of the tracheal or bronchial mucosa (see Nenninger 1901, Paul 1902, Quesnil 1902).

The diphtheroid bacilli and staphylococci which are usually present in cultures from the nose, and the non-hæmolytic streptococci and Gram-negative cocci of the nasopharynx and tonsils, are seldom the only species isolated from swabs taken from these situations. Various other species, including many potential pathogens, are often found. The relative frequency of three such species—*Str. pneumoniæ*, hæmolytic streptococci and *H. influenzæ*—in the nose, nasopharynx, tonsils, and oral cavity in general, is shown in Table 192.

TABLE 192

SHOWING THE FREQUENCY OF CERTAIN BACTERIAL SPECIES IN THE NASOPHARYNX, NOSE, TONSILS AND ORAL CAVITY AMONG A SAMPLE OF THE GENERAL POPULATION (Report 1930.)

Group.	No. of Swabs.		Pneumococcus.	*H. influenzæ*.	Hæmolytic Streptococci.	Gram-negative Cocci.
			Per cent.	Per cent.	Per cent.	Per cent.
I and II .	412	Nasopharynx	40·98	59·01	7·77	97·09
		Nose	16·79	11·68	0·05	12·11
III . .	137	Nasopharynx	42·34	59·54	5·84	97·08
		Tonsil	44·53	54·89	5·11	98·54
IV . .	252	Nasopharynx	49·80	51·01	11·90	95·24
		Mouth-wash	25·70	25·10	11·95	94·82

These figures were obtained during an investigation carried out in Manchester between 1925 and 1927, and refer to a series of observations in which swabs were taken from the nasopharynx of a large number of persons over a total period of 2 years. In a proportion of these persons a second swab was taken at the same time, from the nose in two groups, and from the tonsils in a third group; in a fourth group a general mouth-washing was collected and examined, at the same time as the nasopharyngeal swab was taken. Cultures were prepared on blood agar and Fildes' agar, and mice were inoculated intraperitoneally with each specimen. Figures showing the frequency of Gram-negative cocci are included for comparison. It will be noted that all these species were far less frequent in the nose than in the nasopharynx. This difference is particularly striking in the case of the normal Gram-negative cocci; but it is clear that there is far less

tendency for the pathogenic species to vegetate in the nose than in the nasopharynx. Mouth-washing, in this series of cases at least, appears to be a less effective method of isolating the pneumococcus or the influenza bacillus, but equally effective as regards the hæmolytic streptococci, or the Gram-negative cocci (see also Gundel and Linden 1931, Gundel and Okura 1933, Gundel 1933).

It must not be supposed that these are constant figures. They fluctuate rather widely from time to time and from place to place. Thus the nasopharyngeal carrier rate of hæmolytic streptococci may vary from zero to 20 per cent. in a sample of the normal adult population subjected to repeated swabbing. The fluctuations in pneumococci and influenza bacilli are usually smaller.

Table 193 summarizes the results of a large survey by Straker, Hill and Lovell (1939), which included a group of adults sampled at intervals over a period of seven years. In children, the pneumococcal carrier rates tended to be higher than those recorded in the table, but otherwise the rates were not significantly different.

TABLE 193

SHOWING THE CARRIER RATES FOR CERTAIN BACTERIAL SPECIES IN THE NASOPHARYNX AND NOSE FOR A GROUP OF ADULTS IN AN URBAN POPULATION

Organism.	Nasopharyngeal Carrier Rate.	Nasal Carrier Rate.
	Per cent.	Per cent.
Str. pneumoniæ	20–40	5–15
Hæmolytic streptococci	5–15	< 1
H. influenzæ	40–80	5–10
N. meningitidis	5–20	0–4
Gram-negative cocci other than *N. meningitidis*	90–100	0–15

The rates varied to some extent with the season. In the nasopharynx, pneumococci and to a slight extent *H. influenzæ* were found more frequently in cold, damp seasons than in the dry hot periods; in the nose a similar, but more definite seasonal variation occurred. There was some evidence of an association between these two organisms, whose colonization of the nasopharynx appears to be fairly constant; in the damper colder seasons, they appeared more frequently in the nose of living persons, and in the trachea of persons who had died from a variety of causes. That is, in the summer months the organism was confined largely to the nasopharynx, but in late winter and early spring it tended to colonize downwards into the trachea and forward into the nasal cavity.

The carrier rates for hæmolytic streptococci in the throat are substantially the same in other countries as in Great Britain (see, for example, Bryce and Tewsley 1938, Wu 1941, Boisvert 1942, and Chapter 66). An association of high carrier rates with the possession of tonsils, both in children and adults, has been noted by a number of workers. Thus, Burpee (1937) in an institutional survey records a rate of 27·3 per cent. in persons with tonsils, and 10·3 per cent. in those whose tonsils had been removed (see also Chesterman and Scandrett 1940). Of the hæmolytic streptococci isolated from the throat, a large proportion belong to Lancefield's Group A. The proportion varies from 20–70 per cent. (see, for example, Fleming 1939, Pomales-Lebrón 1940, Harper and Williams 1944), some of the remainder belonging to Lancefield's other groups. It appears that Group A streptococci colonize the tonsils more readily than other hæmolytic streptococci, for in tonsils excised as a routine, Macdonald and others (1940) found Group A streptococci over three times as frequently as those of other groups. Rantz (1941) obtained similar results, and suggested that streptococci other than Group A were to be regarded as transient inhabitants of the superficies of the tonsil, while Group A were colonizers of the tonsillar crypts.

Such studies often show a striking tendency for any given individual to maintain a characteristic nasopharyngeal flora over a considerable period of time. For instance, it is found that one person may carry one or more given types of pneumococcus in the nasopharynx over a period of months and years. Moreover, when pneumococci are isolated from a carrier after a long period, during which samples have given negative results, the newly appearing pneumococcus is of the same type as that originally isolated. In other cases, there may be replacement of one type by another (Gundel and Schwarz 1932, Straker, Hill and Lovell 1939, Smillie *et al.* 1943 ; see also Chapter 77).

In recent years, it has become clear that potentially pathogenic *Staph. aureus* must be included in the normal flora of the anterior nares. Carrier rates of 20 to 50 per cent. are recorded for healthy adults, and rates up to 80 per cent. for healthy nurses working in hospitals or institutions (see, for example, Hallman 1937, McFarlan 1938, Bartley 1941). In most cases, large numbers of *Staph. aureus* are present, and there are indications that the carrier state is relatively persistent (Miles *et al.* 1944), even in persons from whom the cocci are isolated only intermittently, and that the true carrier rate is in the region of 75 per cent.

The characteristic nasopharyngeal flora, with its basic constituents such as streptococci of the viridans type and *N. pharyngis*, together with the fluctuating population of potentially more pathogenic bacteria, is established soon after birth ; and there is no doubt that the infant derives these organisms from the adults or older children in its immediate entourage.

Gundel and Schwarz (1932) have recorded an interesting study of this problem. They examined 426 nasopharygeal swabs from 51 mothers, 645 from their new-born infants, and 66 swabs from nurses in attendance. In accord with earlier observations they found that the nasopharynx was sterile at birth ; but in the first 2 days it became colonized by the usual viridans streptococci, Gram-negative cocci of the *pharyngis* type, occasional diphtheroid bacilli and a certain number of coliform bacilli. By the 2nd or 3rd day pneumococci and influenza bacilli were often present, and their frequency was found to depend on their distribution among the adults in immediate contact with the child, and particularly on their presence or absence in the mother. By serological typing it was often possible to establish the identity of the type of pneumococcus present in the child with that present in the mother (see also Kneeland 1930).

In the same way, infants rapidly acquire *Staph. aureus* from their surroundings. Our colleagues, Dr. Cunliffe and Dr. Stokes (personal communication), have found that within a few days of birth infants in maternity homes and hospitals become heavy nasal carriers, apparently acquiring this organism from nasal carriers among the mothers or nurses ; carrier rates in young infants may be 100 per cent. In older children lower rates are recorded, but they are often higher than those in adults (see McFarlan 1938).

Various workers have described the presence of small Gram-negative, filter-passing, anaerobic bacilli, in suspensions obtained by washing out the nares, nasopharynx and oropharynx with sterile broth (Olitsky and Gates 1921*a*, *b*, Olitsky and McCartney 1923, Mills, Shibley and Dochez 1928, Garrod 1928, Burky and Freese 1931). The evidence suggests that these strains may be differentiated into several distinct types ; but they have not yet been submitted to detailed study from the systematic point of view. The so-called *Bacterium pneumosintes*, at one time regarded as a possible cause of epidemic influenza, apparently belongs to this group. The data at present available with regard to the relative frequency of these bacilli in normal persons, and in those suffering from colds, does not indicate that they play any significant rôle in such

infections. Garrod (1928) has also described the isolation, by the same technique, of minute, Gram-negative, filter-passing, anaerobic cocci

The Normal Flora of the Vagina.

An important distinction must be drawn between the flora of the vulva and vestibulum on the one hand and that of the vagina proper on the other. Except immediately after parturition and during the first few days of the puerperium, the vaginal flora is quite distinct from that of the vulval flora.

The *vulva* of the newly-born child is sterile; organisms make their appearance in about 7 to 8 hours. The normal flora of the vulva is a rich and varied one, and depends largely on the organisms present in its immediate environment. According to Wegelius (1909) it consists of: (1) Obligatory aerobes and aerophilic bacteria, of which the chief types are pseudo-diphtheria bacilli and *M. tetragenus*. (2) Coliform bacilli. (3) Facultative anaerobes, usually more or less susceptible to acid. (4) Bacilli derived from the vagina, including yeasts. (5) Obligatory anaerobes. On agar plates incubated aerobically the commonest organisms to form colonies are staphylococci, diphtheroids, enterococci, sarcinæ, and coliform bacilli. Besides these organisms, yeasts—*Oidium* and *Saccharomyces*—are very common; and the smegma bacillus is not infrequently demonstrable in smear preparations stained with Ziehl-Neelsen. Under anaerobic conditions of cultivation numerous colonies appear, consisting of organisms that have as yet been only imperfectly studied. Pathogenic bacteria are uncommon.

The normal flora of the *vagina* seems to depend largely on the glycogen content of the vaginal epithelium which, in its turn, is dependent on ovarian activity (Miura 1928, Cruickshank and Sharman 1934). The vagina of the newly born child is sterile; organisms make their appearance in 12–24 hours. At first they consist of staphylococci, enterococci, and diphtheroids, but these are often replaced in 2 or 3 days by a practically pure culture of Döderlein's bacillus (see Chapter 31). At this time glycogen is demonstrable in the vaginal epithelium, and the vaginal secretion itself is acid. The occurrence of glycogen appears to be due to the presence of œstrin derived from the maternal circulation. Soon this is excreted in the urine, glycogen is no longer demonstrable in the epithelium, Döderlein's bacillus disappears, and the vaginal secretion reverts towards alkalinity. From now on till puberty the vaginal secretion remains alkaline, and there is a varied flora of staphylococci, streptococci other than *Str. pyogenes*, coliform and diphtheroid bacilli. At puberty glycogen is again deposited in the vaginal wall, the secretion becomes acid, and Döderlein's bacillus establishes itself as the predominant organism. The flora, however, still remains mixed and Döderlein's bacillus is accompanied by many of the organisms that we have just mentioned, as well as by anaerobic streptococci, which appear to be commonly present in the female genital tract (see p. 596). At the menopause, when ovarian activity ceases, the conditions revert to those met with before puberty. Following parturition, and during the first few days of the puerperium, the vaginal flora resembles that of the vulva. At the time of parturition organisms ascend from the vulva to the uterus, where they may be demonstrated for several days (Wegelius 1909).

The vaginal secretion has a marked bactericidal action (see Küster 1929). To a large extent this may be ascribed to the presence of lactic acid, though other factors are probably concerned (Chapter 54). The lactic acid itself is derived from the glycogen, partly perhaps as the result of natural enzymes, but mainly on account of the fermentative activity of Döderlein's bacillus. (Further references:

Döderlein 1892, Segre 1929, Cruickshank and Baird 1930, Pettit and Hitchcock 1933, Cruickshank 1934, Hardy 1941.)

The Normal Flora of the Urethra.

In the anterior urethra of males occasional white staphylococci and diphtheroids may be found, and a short Gram-negative diplobacillus, not to be mistaken for the gonococcus (Kutscher 1909). The female urethra is either sterile or contains a few non-pathogenic cocci. A saprophytic acid-fast bacillus, known as *Mycobacterium smegmatis*, is quite common in the preputial secretion both of males and females; this organism may occasionally find its way into the urine, and be mistaken for the tubercle bacillus.

Normal Flora of the Skin.

Under this heading we shall exclude all the multifarious organisms that may at one time or another be found on the surface of the skin, the numbers and varieties of which depend largely on personal hygiene and environmental conditions. Price (1938) distinguishes this "transient" flora from the "resident" flora, which consists of a relatively few types of bacteria which seem to multiply freely on the skin, and particularly in the sebaceous glands. The "resident" flora, which can generally be cultivated without difficulty, contains large numbers of Gram-positive cocci. Of the numerous types that have been described much the commonest is the white pigmented variety called by Welch (1891) *Staphylococcus epidermidis albus* (see Chapter 25). Another variety, distinguished by its feebler biochemical activity, is found very frequently in scurf, and is known as Gordon's scurf staphylococcus. Occasionally yellow-pigmented staphylococci are found, and sometimes sarcinæ. The great majority of the cocci found on the skin are comparatively non-pathogenic both to human beings and to rabbits, but potentially pathogenic *Staph. aureus* is not infrequently found (Koch 1908). In moister parts, like the axillæ and inguinal folds, Gram-negative bacilli often predominate.

Staph. aureus is not uncommon on the skin of the face and hands, but less common on other parts of the body. The numbers present are usually small, but carrier rates of 5–24 per cent. have been recorded (Vierthaler 1940, Bartley 1941, Smith 1941, Martin 1942).

Skin carriage is more frequent among persons who are nasal carriers. Where typing of the *Staph. aureus* isolated has been possible, either by serological or by bacteriophage tests, similar types have been found in the nose and on the skin in the majority of cases (Gillespie *et al.* 1939, Miles *et al.* 1944). To some extent, therefore, it appears that the skin is continually infected by *Staph. aureus* from the nose. This organism is usually "transient" in Price's sense, but, as Devenish and Miles (1939) showed, some persons carry *Staph. aureus* so deeply in the recesses of the skin that prolonged sweating is required to bring it to the surface. In these cases it appears to be a "resident" (see also Gillespie *et al.* 1939, Vierthaler 1940).

In Chapter 66 we have discussed *Str. pyogenes* as an occasional transient member of the skin flora. There is no reason to believe that it ever forms part of the resident flora of the clinically normal skin; and indeed, in the light of Burtenshaw's (p. 1020) demonstration of natural fatty antistreptococcal substances in the normal skin, it seems unlikely that it could ever do so.

Amongst the other organisms met with are occasional coliform and *Proteus* bacilli, and diphtheroids. The healthy skin appears to have some natural self-

disinfecting mechanism which is responsible for the rapid disappearance of living organisms implanted upon it (see Chapter 45 and Colebrook and Maxted 1933, Arnold and Bart 1934).

In the skin lining the external auditory meatus, as well as the usual staphylococci, diphtheroid bacilli are not uncommon, and sometimes saprophytic acid-fast bacilli, derived from the cerumen, are met with. In the conjunctival sac, organisms are comparatively scanty, and consist chiefly of diphtheroids, such as *C. xerosis*. The conjunctiva may owe its relative freedom from bacteria, in part, to a highly potent lytic enzyme, called by Fleming and Allison (1922) *lysozyme*. These workers found that tears have a high bactericidal power, capable of dissolving certain saprophytic cocci in a dilution of 1/40,000. Further study showed that, with the exception of cerebrospinal fluid, sweat, and urine, this enzyme is distributed to a greater or less extent in practically all the human secretions and tissues, as well as in animal and some vegetable tissues.

Testing the bactericidal power against a large non-pathogenic coccus, called by them *M. lysodeikticus*, they found the blood serum active in a dilution of 1/270, nasal mucus and sputum in 1/13,500, and saliva in 1/300. Extracts of tissues made by grinding up 1 gm. of tissue with 20 ml. of saline showed that the liver and the tonsil were active at a dilution of 1/400, the kidney and skin at about 1/100, while cartilage was active in 1/1,300. Lysozyme dissolves both dead and living organisms, and is more active as a rule against non-pathogenic than against pathogenic bacteria. Its range of activity appears, however, to be very limited, as judged by the small number of bacterial species which it attacks (see Fleming and Allison 1927, Fleming 1929, and Chapter 45).

Bacteria in the Blood and Internal Organs.

We have unfortunately very little information as to the occurrence of bacteria in the blood and viscera in healthy persons. The technical limitations of the usual method of performing blood cultures are such that small numbers of organisms may quite easily escape detection. Even if a sufficiently large sample of blood is withdrawn, it is difficult to ensure that the few organisms contained in it will grow; they may be destroyed by the bactericidal power of the blood or ingested by leucocytes. Moreover the blood that is examined is usually drawn from a peripheral vein, coming from one limited portion of the body, and not therefore so likely to contain bacteria as blood from, let us say, the pulmonary artery through which the blood from all parts of the body has to pass. It has been stated that bacteria frequently gain access to the blood stream under normal conditions, but are filtered off in such organs as the liver, lungs, and spleen, where they are destroyed by cellular and bactericidal action. We do not know how frequently this occurs, what the channels of transit are, or what bacterial species may be concerned. It is also stated that in the new-born infant the epithelial lining of the intestinal mucosa is deficient in places, and that passage of bacteria into the lymph stream and blood is very much more frequent during the first few days of life than it is subsequently. Whether the normal intestinal mucosa of the adult presents a constant barrier to the passage of bacteria is not definitely known; nor is it known why some organisms are able to pass through it very much more easily than others. Experiments made by Arnold (1928) on dogs suggest that the permeability of the mucosa varies from time to time, and is influenced by such factors as the H-ion concentration of the intestinal contents and the amount of protein in the food. It is probable too that variations in the blood supply are of importance. There is, however, good evidence that organisms, particularly

streptococci, pass into the blood stream of patients suffering from focal infections in different parts of the body (Chapter 68).

Examinations of normal mesenteric lymph glands have been few. It seems not improbable that bacteria of different types are frequently absorbed through the intestinal mucosa. Some of these are probably destroyed in the mesenteric glands or the liver; a few may perhaps make their way to the blood stream, from which they will be removed by phagocytic cells. In support of this possibility is the observation that the muscles and viscera of apparently healthy cattle and pigs not infrequently contain bacteria (Zwick and Weichel 1911, Reith 1926).

The now common diagnostic practice of sternal puncture also offers a means of exploring the bacterial content of the reticulo-endothelial system in healthy persons. So far, its bacteriological use has been confined to culture of marrow samples as an aid to diagnosis in infections where the blood culture is sterile. A wide field of experimental work is open to the student who is willing to study the distribution of living organisms in the tissues of apparently normal animals.

CHAPTER 91

THE BACTERIOLOGY OF AIR

In Chapter 59 we have already discussed the apparently conflicting views of Cornet and of Flügge on the respective parts played by dust and by droplets in the spread of pulmonary tuberculosis. More recently observations in this country and in the United States have focused attention on the part played by aerial infection in the causation of other respiratory diseases. Work is now proceeding actively on aerial microbiology, and particularly on the ways in which spread of infection by dust and droplet nuclei can be controlled. We shall attempt to give a brief résumé of the present position, and refer our readers for a fuller account to the Symposium on Aerobiology held at Chicago in 1942 (Report 1942).

Outdoor Air

The degree of bacterial contamination of the outside air depends on a number of factors, such as the density of the human and animal population, the amount of vegetation, the nature of the ground or soil, the temperature and humidity of the atmosphere, the extent and direction of wind currents, and so on. Aeroplane surveys (see Proctor 1934, 1935, Proctor and Parker 1938) show that bacteria in the upper air consist largely of aerobic spore-bearing bacilli, and to a much less extent of organisms belonging to the *Achromobacterium*, *Sarcina*, and *Micrococcus* groups, suggesting that they are derived mainly from soil and surface dust. These organisms can be carried vertically for several miles into the air, and it is possible that they may also travel long distances horizontally. It is conceivable therefore, that certain resistant pathogenic bacteria like the anthrax bacillus, and viruses like the virus of foot-and-mouth disease, might be transmitted from one area or country to another, and serve, on again reaching the ground, as infective agents for man or animals. There is, however, no evidence to prove that this is more than a possibility. On the contrary, most of our observations suggest that infective material is seldom carried for more than short distances by air, or that, if it is, it is too diluted to cause recognizable disease. Though autotrophic bacteria may possibly undergo some multiplication in cloud areas, where moisture and traces of gases such as NH_3 and CO_2 are present, it seems extremely improbable that growth of pathogenic organisms is likely to occur in air. For the medical bacteriologist the importance of the flora of the outside air still remains to be demonstrated. On the other hand, the flora of the air inside buildings, where ventilation is limited, appears to play a major part in the causation of respiratory infection.

Indoor Air

Air-borne bacteria may be distributed in three different forms: (*a*) attached to dust particles; (*b*) contained in gross droplets expelled from the nose and

mouth ; (*c*) present in droplet nuclei, which result from evaporation of the smaller droplets expelled from the nose and mouth.

Dust consists of varying sized particles of animal, vegetable, or mineral origin. The heavier particles fall rapidly to the ground, but can be stirred up by sweeping and draughts ; the lighter particles, which may be 1 μ or less in diameter, remain more or less permanently suspended in the atmosphere. It has been shown by White (1936), Cruickshank (1938), Hare (1941), Thomas (1941*b*) and others that hæmolytic streptococci may be found in the dust of wards harbouring cases or carriers of these organisms. Tubercle bacilli have often been demonstrated in the dust of sanatoria (see Pressman 1937). Wright, Shone and Tucker (1941) and Crosbie and Wright (1941) have demonstrated diphtheria bacilli in large numbers in floor dust collected near diphtheria patients. Under favourable conditions these three organisms have been shown to remain alive and virulent for many weeks. Dust from bedclothes is one of their most prolific sources.

Since Flügge (1899) first drew attention to the rôle of minute droplets expelled from the mouth and nose of phthisical patients in conveying tuberculosis, the concept of droplet-borne infection has been widely applied to the transmission of respiratory disease in general. Of late years renewed interest in its mechanism has been stimulated by the studies of Wells and his colleagues in the United States (Wells 1934, Wells and Wells 1936, 1938). The observations of these workers, and of others such as Weyrauch and Rzymkowski (1938) and Jennison (1942), have amplified the earlier findings of Lange and Keschischian (1925) and Strauss (1926), and have thrown fresh light on the size and fate of droplets emitted from the mouth during sneezing, coughing, whistling, singing, and talking. A brief abstract of the earlier reports has already been given in the chapter on tuberculosis (p. 1313), but it will be well here to expand this description in the light of more recent work.

During a sneeze it is calculated that something like 20,000 droplets are expelled, mainly through the closed teeth, at an initial velocity of about 150 feet per second (Jennison 1942, Hatch 1942). Their diameter varies from about 10 μ to over 1 mm. The fate of these droplets depends on their size. The larger ones are projected some distance but fall to the ground before they can evaporate completely. The smaller ones, owing to the greater ratio of their surface to their volume, travel only a short distance and evaporate quickly (see Table 194).

TABLE 194

EVAPORATION TIME OF WATER DROPLETS IN UNSATURATED STILL AIR AT 22° C.
(Taken from Jennison 1942, modified from Wells 1934)

Diameter of Droplet in μ.	Evaporation Time in Seconds.
2,000	515·0
1,000	129·0
500	32·0
200	5·2
100	1·3
50	0·31
25	0·08
12	0·02

Droplets 1 mm. in diameter, if projected from the mouth of a man of average height, fall in a curved trajectory and reach the ground in about 15 feet. On

the other hand, droplets less than 0·1 mm. in diameter possess too little kinetic energy to enable them to travel more than a very short distance from the mouth, and are so little affected by gravitation that they evaporate before they have fallen to any appreciable extent. On evaporation, they become converted into what Wells calls "*droplet nuclei*," which behave very much like minute particles of smoke. In absolutely still air they fall at the rate of probably 1 to 3 feet per hour, but in the ordinary atmosphere they remain suspended almost indefinitely, being dependent for their transportation on air currents. It has been shown experimentally that micro-organisms attached to droplet nuclei are rapidly dispersed throughout rooms and even buildings, and are inhaled by anyone breathing air containing them (Wells and Wells 1936).

Trillat (1938) describes an interesting experiment in which he atomized one litre of a fluid suspension of *Chromobacterium prodigiosum* in a central court of the Pasteur Institute in Paris. A hundred agar plates were exposed for more than 100 metres around. Every single plate became infected, even those placed to windward of the court. Droplet nuclei, when inhaled, may be caught up by the nasopharyngeal mucosa, but, judging from the observations of Wells and Lurie (1941) on rabbits, a high proportion of them appear to reach the lungs. Available evidence, however, suggests that only particles less than 10 μ in diameter are able to pass directly into the alveoli. Since it is estimated that probaby 20–40 per cent. of droplets expelled in a sneeze are less than 50 μ in diameter and therefore evaporate to droplet nuclei within a fraction of a second, it follows that something like 4,000 to 8,000 droplet nuclei, many of them probably containing bacteria of respiratory origin, result from a single sneeze. (For photographs of droplet expulsion in a sneeze, see Weyrauch and Rzymkowski 1938, Bourdillon and Lidwell 1941, Jennison 1942.)

Droplets are also expelled, though in much smaller numbers, during coughing; as in a sneeze, the vast majority are not projected more than 2 or 3 feet. In talking, particularly in the pronunciation of sharp consonants like p, b, t, f, k and s, droplets are often expelled through the teeth; their average size is larger than of those in a sneeze, but their initial velocity is lower, and few travel more than a foot.

The part played by air-borne droplet nuclei in the spread of respiratory infection has been studied by Wells and Wells (1942), and is discussed in Chapter 59.

Measurement of Air Contamination

Several methods have been devised for measuring the bacterial contamination of the atmosphere. The results given by different methods are often widely at variance, mainly because of the differences in methods of sampling.

One of the simplest ways is to expose a series of agar plates in different parts of the room for a given time. Under ordinary conditions the number of colonies that develop is determined mainly by the larger dust particles and droplets, which fall to the ground in a more or less vertical direction. Unless the air is quite still and the plates are left for some hours, the droplet nuclei are scantily represented.

In an attempt to obtain a more representative sample of the smaller suspended particles, Wells, Phelps and Winslow (1937) devised an air centrifuge in which the bacteria from large measured volumes of air are deposited by centrifugal force on to the sides of a rotating cylinder lined with nutrient agar. Though this machine picks out practically all particles having a settling velocity in still air

greater than 30 feet per hour, it has been found experimentally that recovery of the smallest particles of a finely atomized culture, having a settling velocity of about 1·8 feet per hour, is only about one-third complete (Wells, Phelps, Robertson and Winslow 1942). (See also Wells 1943.) A simpler apparatus was devised by Hollaender and Dalla Valle (1939), in which measured volumes of air are drawn through a funnel and allowed to play on agar plates; and by Wheeler, Foley and Jones (1941), in which measured volumes of air are bubbled through broth in a flask, and the bacterial content of the broth is determined by plating. Various modifications of the Wells air centrifuge have been described by Finn and Powell (1942), who give an elementary mathematical treatment of the principle underlying its construction and use.

A simple and effective device for the collection and counting of air-borne bacteria is Bourdillon's slit sampler (Bourdillon *et al.* 1941). Air is sucked through a slit 0·25 mm. wide and impinges on to the surface of a rotating agar plate immediately beneath. The rate of suction is adjusted to 1 cubic foot of air per minute, and samples of 2–10 cu. ft. are collected, depending on the bacterial content of the atmosphere. Elliott (1941) devised an entirely different method, which has not yet been properly developed. Its essential features are first, the trapping of suspended particles by drawing the air sample through a water-vapour mist, and second, the condensation of water on any particles left in suspension by cooling the saturated air. This latter principle is derived from the Wilson cloud chamber, in which the path of electrons is made visible by depositing on them water droplets condensed from a saturated atmosphere by a sudden reduction in pressure.

For estimating the degree of nasopharyngeal pollution of the air, Gordon (1902–03) long ago, in his study of the ventilation of the House of Commons, suggested that *Str. viridans* should be used, in much the same way as *Bact. coli* is used for measuring the excretal pollution of water. This suggestion has been revived by American workers (Buchbinder *et al.* 1938, Wells, Wells and Mudd 1939), and may prove of value as soon as a reliable selective medium is available. *Str. viridans* is also useful for testing the efficacy of bactericidal agents designed to destroy potentially pathogenic micro-organisms in the air. It can be sprayed into a closed room, and the disinfection rate estimated by plate counts on air collected at measured intervals.

Measures for Controlling Air-borne Infection

As Andrewes (1940) points out, no method for the control of air-borne infection is as satisfactory as proper spacing of individuals combined with adequate ventilation. These enormously reduce the risk of infection, whether from droplets, droplet nuclei, or dust. When they cannot be achieved, other methods may be tried as substitutes. As yet the study of counter measures to air-borne infection is still in its infancy. The brief summary that we give here can do little more than indicate the directions in which research is proceeding.

Dust-borne Infection.—In hospital wards a large amount of dust is derived from blankets; bacteria-containing particles of fluff are freely liberated whenever the blankets are shaken. These particles rapidly settle on the floor, but rise again in a cloud on sweeping. Van den Ende, Lush and Edward (1940) found that if the floor was treated with spindle oil, the dust particles became sticky and mutually adherent, so that they could be swept away without being dispersed

again into the air. The effect of the oil was purely mechanical; it had no germicidal action on the organisms. Judged by the number of haemolytic streptococci cultured from the air after sweeping of the floor, oil treatment proved very effective. Thomas (1941*a*), who studied the air flora in canteens and hospital wards over a period of some months, found that the result of oil treatment of wooden floors was to reduce the number of organisms dispersed into the air on sweeping by about 80 per cent. The oil can be applied to wooden or to linoleum floors, but not to rubber, cement, or concrete. A fresh application has to be made every 6 or 8 weeks.

Observations by van den Ende and Spooner (1941), however, showed that, if bacterial contamination of the air in hospital wards was to be adequately controlled, treatment of the floor alone was insufficient. The bedclothes, particularly the blankets, which constituted the source of the dust, had to be treated too. It proved possible to do this by soaking them in 30 per cent. liquid paraffin in "white spirit," followed by removal of the excess in a hydro-extractor (see van den Ende, Edward and Lush 1941). Woollen materials retained about 2·5 per cent. of their weight of oil, and cotton materials about 6·5 per cent.; they were not perceptibly oily to the touch. In this way the heavy contamination of the air that normally accompanies bedmaking was avoided. Further work by van den Ende and Thomas (1941) showed that liquid paraffin in white spirit could be replaced by technical white oil emulsified very finely in water by means of suitable wetting agents, which had the advantage of imparting to the bedclothes potent bactericidal activity. The use of these oil-in-water emulsions resulted in a 99 per cent. reduction in the number of organisms liberated during bedmaking. In practice, Wright, Cruickshank and Gunn (1944) found that in order to control streptococcal cross-infection in measles wards it was essential to oil not only the floors, but also the bedclothes, sleeping garments, towels and similar articles. When this was carried out thoroughly, a substantial reduction in the cross-infection rate and in the middle-ear complication rate was effected (For technique of laundering garments with oil, see Harwood, Powney and Edwards, 1944).

Droplet-borne Infection.—When people are working in close contact with each other, infection conveyed by droplets may be controlled to some extent by the use of face masks. As demonstrated by actual photographs, masks made of fabric alone are not completely impermeable to the droplets expelled during sneezing; the larger droplets become enmeshed, but many of the smaller droplets pass through and are propelled for some distance into the air (Jennison 1942). On the other hand, if a layer of cellophane is sewn into a pocket between the inner and outer layers of a double-folded muslin mask, the passage of bacteria is obstructed (see Devenish and Miles 1939). It is very doubtful, however, whether any mask that can be worn with reasonable comfort can be relied on to prevent the inhalation of organisms in the form of droplet nuclei (Andrewes 1940).

Infection carried by Droplet Nuclei.—Measures to control true aerial infection are designed to destroy the micro-organisms attached to droplet nuclei, which are floating freely in the atmosphere. Hitherto, the main lines of attack have been (1) by ultra-violet irradiation, and (2) by disinfectant sprays and vapours.

1. *Ultra-violet Irradiation.*—The chief protagonists of ultra-violet irradiation have been Wells and his colleagues in the United States (Wells and Wells 1936, 1938, Wells 1940, 1942, Wells, Wells and Wilder 1942). The method may be applied in various ways. (*a*) Air may be re-circulated through ducts fitted with

sources of ultra-violet light and returned to the room. Though organisms in droplet nuclei may be destroyed by this method, many of those attached to dust particles will resist attack and enter the room still viable. It is advisable, therefore, to pass the air first through a cloth filter to remove the dust particles before exposing it to the ultra-violet rays. In this form, the method may be of value for supplying air to operating theatres, cinemas, restaurants and railway coaches. (*b*) Provided the eyes of the occupants are screened, the room may be irradiated directly. Very satisfactory results have been claimed by Hart (1941) from the use of this method in operating theatres. (*c*) Instead of exposing the whole room to ultra-violet light, irradiation may be restricted to the space above the level of the heads of the occupants whose eyes therefore require no protection. This method has been used with apparent success in the control of air-borne infection in school-rooms (Wells, Wells and Wilder 1942); but observations by Schneiter and his colleagues (1944) in a training school for boys showed that ultra-violet irradiation of the upper air of the dormitories had no appreciable affect on the incidence of air-borne disease, as judged by hospital admission records. (*d*) So-called ultra-violet light barriers may be used in hospitals to prevent the air of cubicles from becoming infected with the air of the general ward. In conjunction with air conditioning, this method is said to have given satisfactory results in the Cradle at Evanston, Ill. (Rosenstern 1942); but in an infants' hospital at Boston it failed to diminish the incidence of cross-infection (Brooks *et al.* 1942). In Lurie's (1944) hands an ultra-violet light barrier proved successful in preventing cross-infection of normal rabbits in one set of cages with tubercle bacilli from infected rabbits in adjacent cages.

2. *Disinfectant Sprays and Vapours.*—In the early days of antiseptic surgery Lister introduced a carbolic spray to sterilize the air over the wound. It is doubtful how far it was effective. Hewlett (1939), for example, found that to kill typhoid bacilli on paper slips, it was necessary to vaporize 35 gm. of phenol per 1,000 cu. ft. of air, and even then an hour's exposure had to be allowed. It is probable that, had the bacilli been atomized, a lower concentration of phenol for a shorter time would have proved effective; but since more powerful germicides than phenol are now known, the interest of the carbolic spray is mainly historical.

Though sulphurous acid and formalin vapours were used for terminal disinfection in isolation hospitals and sick-rooms, little progress in the destruction of bacteria in the air of occupied rooms appears to have been made till Douglas, Hill and Smith (1928) showed that it was possible to bring about the rapid death of *Bact. coli* in the atmosphere by means of a sodium hypochlorite solution sprayed into the air in very high dilution. In spite of this impressive result, no general interest in the possibilities of aerial disinfection was aroused till the publication of Wells's papers in 1934 and 1936 on the nature and significance of air-borne bacteria in the causation of respiratory disease. In 1938 appeared Trillat's paper on bacterial aerosols, and Masterman's paper on the purification of the air of inhabited rooms by a hypochlorite spray. Since then, intensive study has been devoted by several workers to the problem of finding a suitable chemical agent for disinfection of the atmosphere. Some of the more promising substances may be referred to here.

(*a*) Sodium hypochlorite. Masterman (1938, 1941) found that a reduction of over 99 per cent. in the bacterial content of the atmosphere could be brought about by atomizing 1 gm. of a 1 per cent. sodium hypochlorite solution in 40,000,000 ml.

of air. Evidence suggests that so far as bacteria of nasopharyngeal origin are concerned, such a high percentage reduction could hardly be expected.

Andrewes (1940) states that 5 ml. of a 1 per cent. hypochlorite solution were required to kill rapidly 95 per cent. of streptococci suspended in the air of a room of about 1,000 cu. ft. capacity; this gives a concentration of only 1 in 5·7 million. Pulvertaft (1944) made similar observations. Bourdillon, Lidwell and Lovelock (1942) found that 2·1 ml. of 1 per cent. sodium hypochlorite solution per 1,000 cu. ft., i.e. 1 in 13·5 million, killed almost all the bacteria projected into the air by sneezing in 3 to 4 minutes. Challinor (1943) observed a reduction of about 33 per cent. of the aerial bacteria, as measured by the slit sampler, after spraying a room with 1 per cent. hypochlorite solution in the proportion of 11 ml. to 1,000 cu. ft., i.e. a concentration of only 1 in 2·6 million. Edward and Lidwell (1943), using hypochlorous acid gas, found it necessary to use an initial concentration of 1 in 800,000 to destroy 90–99 per cent. of suspended influenza virus particles. Nevertheless, it is clear that sodium hypochlorite or HOCl has a powerful disinfectant action on most non-sporing pathogenic bacteria.

The effective concentration of sodium hypochlorite is influenced by a number of factors. A low relative humidity and a high content of organic matter in the air are both unfavourable. So also is the presence of phenol or cresol vapour. HOCl attacks metal, and is decomposed by organic matter, so that metal sprays should not be used, nor should the solution be allowed to come into contact with rubber or wool. Hypochlorite sprays should be avoided in rooms containing certain electrical equipment, such as telephone switchboards. Elford and van den Ende (1945) have pointed out the disadvantages of using hypochlorite for continuous disinfection of the air, and suggest the use of hypochlorous acid gas in its place. Even so, however, the corrosive action on metals when the gas is used at the optimum relative humidity of 70–90 per cent. may be a serious practical objection.

(*b*) Resorcinol in glycerol was found by Pulvertaft and Walker (1939) to be very effective, though too expensive for routine use. Hexyl resorcinol is also valuable. According to Twort and Baker (1942), it kills more slowly than resorcinol, but acts in a lower concentration and persists longer. It is therefore to be preferred when air changes are infrequent and overcrowding is not severe. Hexylresorcinol, in the form of a 10 per cent. solution in propylene glycol together with 0·05 per cent. sulphonated lorol, was found by Twort, Baker, Finn and Powell (1940) to be even more effective.

(*c*) Propylene glycol. This substance, which was used by Twort and his colleagues as a solvent, has itself excellent disinfectant properties. Robertson, Bigg, Puck and Miller (1942) brought evidence to show that 1 part of propylene glycol vapour in 2 to 4 million parts of air produced complete and almost immediate sterilization of an atmosphere into which pneumococci, streptococci, staphylococci, *H. influenzæ*, and influenza virus had been sprayed. Favourable results in preventing cross-infection in children's wards have been reported for propylene glycol vapour by Harris and Stokes (1942). Puck, Robertson, and Lemon (1943), who studied propylene glycol and triethylene glycol, found that both of these compounds acted best at a room temperature below 80° F. and at a relative humidity of 45–70 per cent. At low humidities the bacteria-containing droplets dried up so quickly that the glycol vapour did not condense readily on them. At high humidities water vapour condensed as well as the glycol vapour and thus diluted it. It is clear from these observations that the glycol vapours acted best on sprayed bacteria-containing droplets. Organisms in dust proved resistant.

Essentially the same conclusions were reached by DeOme and his colleagues (1944), who found that the germicidal power of triethylene glycol vapour decreased as the temperature rose from 28° to 37° C. and as the relative humidity deviated from 45 per cent. They noted also that, to produce a given reduction in the numbers of *Salm. pullorum* sprayed into the air, a concentration of propylene glycol 100 times that of triethylene glycol was required.

(*d*) Balsamic smokes. The germicidal action of the smoke given off by smouldering cardboard, tobacco, and incense was noted by Twort and Baker (1940). Incense was found to be the most effective; 1 part in 160 million of air destroyed salivary organisms within 15 minutes.

The mode of action of the vaporized disinfectants is subject to controversy. According to Trillat (1938), Pulvertaft and Walker (1939), and Twort and his colleagues (1940), atomized disinfectants exert their action in the form of minute droplets—hence the term aerosol coined by Trillat—which come into contact with the suspended bacteria. Other workers maintain, on the contrary, that they act as simple gaseous disinfectants. Masterman (1941), for example, points out that minute droplets of the size postulated by Twort, namely 0·4–1·0 μ in diameter, would evaporate in a fraction of a second (see p. 2003), and would therefore no longer be in the aerosol or mist form. So far as sodium hypochlorite is concerned, Masterman is of the opinion that its disinfectant action is due to gaseous hypochlorous acid set free by the carbon dioxide in the air. Similarly, there is growing evidence that propylene glycol acts essentially in the gaseous form. Vaporization of this substance by heat is just as effective as spraying it in the form of a mist (see Robertson, Bigg, Puck, Miller and Baker 1942). Moreover, calculation shows that the maximum number of contacts possible between the disinfectant and the bacterial droplets is insufficient to account for the extreme rapidity of sterilization so long as the disinfectant is present in the form of an aerosol. If, however, the aerosol droplets are assumed to evaporate almost at once, then sufficient molecules of gas will be liberated within 2 or 3 seconds to produce a lethal concentration of propylene glycol in the bacteria-containing droplets. This explanation is also in accord with the observation that, in the form of a liquid, propylene glycol has a very low bactericidal action, whereas in vaporized form it is among the most active disinfectants known. The term aerosol is somewhat misleading, and should probably be reserved for minute droplets of oily substances that do not evaporate in the atmosphere.

It may be mentioned that both to ultra-violet light and to disinfectant vapours Gram-negative bacilli are more susceptible than Gram-positive cocci; and that organisms of whatever nature are harder to kill when dried on to particles of dust than when present in the form of droplet nuclei.

The Control of Respiratory Infection

It is as yet too early to assess the value of the different methods just discussed for the control of respiratory disease. One of the great difficulties is to ensure the continuous absence of pathogenic organisms from the atmosphere during the 24 hours of each day. In the prevention of enteric infections reliable measures are available for the destruction of the causative organisms in water and in milk; and provided due sanitary care is exercised, food should seldom be contaminated except by accident. In this way the entire population of a city can be more or less efficiently protected. But with respiratory disease, the problem is far more

difficult. Even if good ventilation is provided in the factory, measures are taken to allay dust, overcrowding is avoided, and pathogenic organisms in the air are destroyed by ultra-violet irradiation or by disinfectant gases, the operatives are still exposed to the risk of infection in the buses, trains, and tubes that take them to and from their work, in the shops where they buy their food and other necessaries, in the places of amusement that they frequent, and probably for 10 or 12 hours of every day in the houses where they live and to which their children return bringing infection with them from school. Whether it will ever prove practicable to afford continuous protection to the worker in all these varied situations, it is impossible to say. To do so will require an intensive and prolonged education of the general public, greatly improved ventilation of houses and other buildings, and a willingness on the part of both private persons and of public authorities to incur the necessary expenditure to combat the spread of aerial infection.

For the present it will probably be wise to confine our attention to the prophylaxis of air-borne infection in such situations as operating theatres, hospital wards, out-patient departments, and certain institutions, where reliable bacteriological and epidemiological data on the type and incidence of respiratory disease can be collected. By this means we should find out in course of time how effective different measures are, alone or in combination, and be in a better position to decide whether their extension to other fields is desirable.

The prophylaxis of respiratory disease is a formidable problem, which has in the past seemed almost insuperable. We may find, however, that the complete destruction of all pathogenic bacteria in the air is not necessary, at any rate in the prevention of some diseases. It may suffice to reduce their numbers to below a critical level at which, provided they are not inhaled by the individual too rapidly or too frequently, the normal defences of the body can be trusted to deal with them. It is unlikely that all respiratory disease will be avoided. Measles and influenza will probably defeat our best endeavours for many years to come. But the abolition, at least in epidemic form, of scarlet fever and of all the varied streptococcal infections associated with it, of cerebrospinal meningitis, of whooping cough, of primary pneumococcal pneumonia, and even of pulmonary tuberculosis, though at present only a vision, may, with the application of our knowledge and in a time that is not too far distant, come to be realized as an achievement within our power.

CHAPTER 92

THE BACTERIOLOGY OF WATER, SHELL FISH, AND SEWAGE

WATER

Bacterial Flora in Water.

It is convenient to divide the bacteria found in water into three groups:

A. Natural Water Bacteria.

In this group are included those organisms that are commonly found in waters free from gross pollution. They may be subdivided as follows:

Bacilli.

(1) Fluorescent
- Gelatin liquefied. *Ps. fluorescens liquefaciens.*
- Gelatin not liquefied. *Ps. fluorescens non-liquefaciens.*

(2) Chromogenic
- Red pigment. *Chr. prodigiosum, Chr. indicum.*
- Orange „ *Chr. aurescens.*
- Yellow „ *Chr. ochraceum.*
- Violet „ *Chr. violaceum.*

(3) Non-chromogenic: These organisms belong mainly to the *Achromobacterium* group. They are sometimes divided up according to their reactions on gelatin and milk; but they have so far not received sufficient study to render their classification possible. Gram-positive, spore-bearing aerobes, which produce acid and gas in lactose, appear to be not uncommon (Greer 1928, Porter *et al.* 1935). Members of the coli-typhoid group are not natural inhabitants of entirely unpolluted waters.

Cocci.

(1) Chromogenic. Generally yellow pigment formed.

(2) Non-chromogenic. *M. candicans, M. aquatilis, M. coronatus.*

Sarcinæ.

Chiefly *Sarcina lutea.*

B. Soil Bacteria.

These organisms, though not normally inhabitants of water, are frequently washed into it during heavy rains. Most of them belong to the group of aerobic spore-bearing bacilli, such as *B. subtilis*, *B. vulgatus*, *B. megatherium*, and *B. mycoides*. Others, such as *Bact. aerogenes* and *Bact. cloacæ*, which appear to live most frequently on grain and plants, and which may conveniently be treated as soil organisms, are aerobic non-sporing bacilli. By the use of special media other organisms, such as the nitrifying bacteria, may be isolated.

C. Sewage Bacteria.

Many of the organisms in this group are normal inhabitants of the intestine of man and animals. Others live chiefly on decomposing organic matter of either animal or vegetable origin. Occasionally pathogenic organisms are included.

(1) *Intestinal Bacteria.*
Bact. coli group.
Streptococcus faecalis.
Cl. welchii.
Pathogenic organisms, such as *Salm. typhi* and *V. cholerae.*

(2) *Sewage Bacteria proper.*
Proteus: Pr. vulgaris.
Anaerobic spore-bearing bacilli: *Cl. sporogenes.*

Studying about 800 strains of bacteria isolated from lakes and streams in the English Lake District, all but one of which were subject to both human and animal pollution, Taylor (1912*b*) found that about 95 per cent. were Gram-negative rods, about 4 per cent. Gram-positive spore-forming rods, and less than 1 per cent. cocci. A large proportion of the organisms were chromogenic; growth on ordinary media was often very poor, and biochemical activity was relatively slight. Taylor points out that these characters differ from those commonly found in soil bacteria; he maintains, in effect, that there is a natural water flora distinct from the organisms washed in with soil.

(For the classification of water organisms see Fuller and Johnson 1899, Boyce and Hill 1900, Jordan 1903, Cornwall 1914.)

Factors determining the Kinds and Numbers of Bacteria in Water

A. Type of Water. Waters may be divided according to their source into (1) surface and (2) deep waters. The former comprise all those that are found on or near the surface of the earth, and that have not been filtered through any considerable thickness of soil; the latter comprise those which, in order to reach the underground stratum that they occupy, have percolated, often for several hundred feet, through porous layers of soil. Since surface waters are frequently exposed to contamination from dust, soil, sewage, factory wastes, and other decomposing organic matter, they may contain large numbers of bacteria, many of which are of intestinal origin. Deep waters, on the other hand, are generally pure, having had most of their surface contaminants filtered off on their downward passage through the soil; and, though it is not unusual to find bacteria in larger numbers than one would expect, these are generally of a harmless type.

(1) Surface Waters.

(*a*) *Rain.*—In falling to the earth, the raindrops come into contact with particles of suspended dust, and carry these down with them. The more dust there is in the atmosphere, the greater is the bacterial count. The figures in Table 195 have been recorded at the Montsouris Observatory at Paris.

From a comparison of these two columns, it will be seen that on the whole the greatest numbers of organisms in rain are found during the dusty months of June, July, August, and September. Montsouris is situated on the outskirts of Paris; in the centre of the city the air was found to contain 6,040 bacteria per cubic metre, and the rain 19,000 bacteria per litre.

TABLE 195

	Bacteria per cubic metre of Air at Montsouris Average for 10 Years	Bacteria per litre of Rain Water at Montsouris. Average for 2 Years.
January	160	8,000
February	145	1,320
March	225	2,920
April	310	2,140
May	305	2,440
June	355	5,600
July	465	5,600
August	455	8,300
September	310	5,770
October	190	3,220
November	195	3,250
December	165	4,330
	Mean 275	Mean 5,300

In the open country the organisms may not exceed 10 or 20 organisms per litre of rain.

(*b*) *Snow.*—This tends to be less pure than rain, probably because the snow-flakes have a greater surface on which to collect suspended particles in the atmosphere ; and also because their low temperature conduces to the survival of bacteria. In snow situated on the tops of high mountains, where it will be remembered that Pasteur found the air to be practically sterile, there are hardly any organisms.

(*c*) *Hail.*—Curiously enough, hail contains more bacteria than either rain or snow. Belli (1902) examined hail that fell in Padua during July, 1901, and found no fewer than 140,000 organisms per litre. Examination of the bacteria showed that they belonged to nine different types. During the formation of hail, it seems probable that rapidly ascending currents of air carry the raindrops up into a region of the atmosphere where they are solidified ; falling down they are melted, and again swept upwards and frozen. After they have been frozen and thawed a number of times the hailstones are thrown out on the periphery of the storm centre and finally come to earth (Mason 1902). It is suggested that the air currents carry up to the cloud region quantities of dust, which is thus incorporated in the hail. It is difficult to explain otherwise the presence in it of vegetable cells, and of fluorescent and soil bacteria.

(*d*) *Ice.*—The number of organisms in ice depends on the nature of the water from which the ice is formed. With the exception of the ice of glaciers, it is generally impure. Its low temperature is favourable to the survival of most bacteria ; hence the self-purification that occurs in waters on storage occurs hardly at all, or very slowly, in ice. For a short review on the bacteriology of ice, see Jensen (1943).

(*e*) *Shallow Wells.*—If protected from contamination in the immediate vicinity by brick sides, and if provided with a pump, shallow wells may contain relatively few bacteria ; but the water of an open draw-well, subject to the influx of dust and of surface washings, is generally very impure. In an examination of over 50 shallow wells, Savage (1906) found that the gelatin count at 20° C. varied from 100 organisms to 20,000 or more per ml. ; and the agar count at 37° C. from less than 10 to over 100 per ml.

(*f*) *Upland Surface Waters.*—If derived from open moorland that is protected from human and animal excretions, these waters are relatively pure. Most of the organisms they contain belong to the soil group of bacteria. The agar count is generally low, not more than 10 or 20 per ml. The gelatin count is fairly high, up to 1,000 per ml.; after heavy rainfall it may rise to several thousands.

(*g*) *Rivers.*—In most countries rivers are heavily contaminated, and contain, not only the natural and the soil bacteria, but large numbers of organisms derived from sewage. In the raw Thames water taken at Hampton during 1906–11 Houston (1913) found the average number of colonies per ml. on gelatin to be 4,310, and on agar 368; typical *Bact. coli* was found in 49·3 per cent. of samples of 0·1 ml. and in 99·2 per cent. of samples of 100 ml.

(*h*) *Lake Waters.*—Owing to the natural storage of water in lakes, there is a continuous process of self-purification occurring; hence lake water is purer than the streams that feed it. Water taken from the middle of the lake contains fewer organisms than that taken near the shore. Lake Geneva contains as many as 150,000 bacteria per ml. near the shore, but further out as few as 38 (Marshall 1921). In Lake Windermere Taylor (1940) found that within 200 metres of the entry of the main river the plate count was 200 times less than at the mouth of the river itself.

(*i*) *Sea Water.*—The number of bacteria in sea water is generally less than in fresh. Russell (1892) found that the water taken near the coast in the Gulf of Naples contained 70,000 organisms per ml., but 4 kilometres out there were only 57. In deep sea the bacteria seem to be distributed evenly, there being almost as many near the bottom as on the surface. The ooze on the bed of the ocean is very rich in bacteria; Russell found 20,000 organisms per ml. Fresh sea water is said to destroy sewage bacteria fairly rapidly (ZoBell 1936), though in estuaries they may remain alive for a considerable time. Part of the destructive action may be due to the activity of protozoa, copepods, and various other lower animal forms (Waksman and Hotchkiss 1937).

(*j*) *Mineral Springs.*—These tend to be relatively pure, and most of the organisms found in water derived from them come from imperfectly sterilized bottles (Duhot and Hutin 1933). The reaction of these waters varies considerably. Bance and Caillon (1929) give the following figures: Badoit pH 6·1, Vals pH 6·05–6·4, Vichy pH 6·4–6·9, Contrexéville pH 6·9–7·0, Vittel pH 7·1, Rubinat pH 7·3–7·6.

(2) DEEP WATERS.—Some of the purest waters that we know come from deep wells and springs. Fifteen driven wells in the neighbourhood of Boston, Mass., contained an average of only 18 colonies per ml. (Prescott and Winslow 1913). In a period of 7 consecutive years, out of 1,565 samples of waters from the deep wells in Kent, Houston found *Bact. coli* in only 5·7 per cent., even when 100 ml. were examined. The purity of springs depends mainly on their source and surroundings. In waters which have percolated through thick strata, the flora differs from that in surface waters; the organisms develop slowly at room temperature, there are few liquefying colonies, and chromogenic organisms are relatively numerous (Prescott and Winslow 1913).

B. Nutrition.—The amount of available food supply is probably the most important factor of all in determining the number of bacteria in a given water. When organic matter is plentiful, organisms abound; when it is scarce they are few, and tend to die out.

C. Temperature.—The effect of temperature varies with the amount of organic matter present. A rise of temperature in a water containing an ample food supply for the bacteria causes them to multiply rapidly: but when the organic matter is small in quantity, a rise in temperature has the reverse effect; this is probably due to early exhaustion of the food supply, and the consequent diminution in rate of multiplication of the bacteria.

A low temperature, independent of the amount of organic matter present, favours the survival, though not the multiplication, of bacteria. Houston (1913) added typhoid bacilli to raw Thames water, and maintained the samples at temperatures varying from 0° C. to 37° C. The initial number added was 103,328 per ml. of water. Table 196 shows how much more rapid was the death of the organisms at 37° C. than at freezing-point. Hamilton (1935), who made observations on the Whangpoo river, found that in the short run from Shanghai to Woosung there was a diminution of 16 per cent. in the colon bacteria during the winter months, and of no less than 97–99 per cent. during the summer months.

TABLE 196

INFLUENCE OF TEMPERATURE. (Houston 1913.)

Degrees.	No. of Bacilli per ml. surviving after weeks.								
	1.	2.	3.	4.	5.	6.	7.	8.	9.
0° C. . .	47,766	980	65	34	3	3	2	1	0·0
5° C. . .	14,894	26	6	3	0·3	0·1	0·0	—	—
10° C. . .	69	14	3	0·3	0·0	—	—	—	—
18° C. . .	39	3	0·4	0·0	—	—	—	—	—
27° C. . .	19	0·1	0·0	—	—	—	—	—	—
37° C. . .	5	0·0	—	—	—	—	—	—	—

D. Light.—It has been asserted that the ultra-violet rays of the sun play an effective part in destroying micro-organisms in water. Procaccini (1893) placed drain water, from which the coarser particles had been removed, in glass cylinders 50 cm. deep, and exposed them for 6 hours to the Italian sun in June. A control cylinder was protected from the light (Table 197).

TABLE 197

	Insolated Cylinder. Bacteria per ml.	Darkened Cylinder. Bacteria per ml.
Before Exposure:		
Surface	4,900	4,900
Middle	4,510	4,510
Bottom	6,781	6,781
After Exposure:		
Surface	0	7,261
Middle	2	9,051
Bottom	8	12,591

The water in the exposed cylinder was practically sterilized; that in the protected cylinder contained rather more organisms than at the start of the experiment.

It would appear that under laboratory conditions the actinic rays of the sun may exert a bactericidal effect. In nature, however, the conditions are altered. One of the main factors hindering the rays is the opacity of the water, which prevents their penetration for more than a short distance. Even in clear water, it is doubtful if they are active for more than a distance of 5 feet from the surface. Another factor is the movement of the water, which may prevent any single organism from being subjected to the rays for a sufficient time to kill it. In this country it is probable that sunlight has little, if any, effect in diminishing the bacterial content of waters. Ultra-violet rays generated from a mercury vapour lamp have, however, been used in the artificial purification of water (Thresh and Beale 1910, Foulds 1911); for this purpose it is essential for the water to be exposed in shallow layers.

E. Acidity.—Winslow and Lochridge (1906) showed that *Bact. coli* in tap water was destroyed by 0·0123 normal hydrochloric acid in 40 minutes. This corresponded to 12·8 parts per million of dissociated hydrogen. Organic acids were likewise bactericidal, but usually in a higher concentration; their effect appeared to be due, not only to the dissociated hydrogen, but also to the undissociated molecule or to the anion (see Chapter 5).

Many natural waters have an acid reaction. In the moorland streams this acidity is due chiefly to the presence of peaty acids—the so-called humic and ulmic acids. Though it is difficult to estimate the effect of acidity on the destruction of bacteria and on the inhibition of their growth, there is little doubt that it does play a considerable part in purifying some waters.

F. Salinity.—The antiseptic and disinfectant action of salts has already been described in the chapter on Disinfection. It is not necessary here to do more than remind the reader of the inimical effects on bacterial growth and survival that certain salts may exercise. It is probably this factor that accounts for the difference both in the numbers and in the types of bacteria found in sea water.

G. Dissolved Oxygen.—Whipple and Mayer (1906) found that *Salm. typhi* and *Bact. coli* remained viable in sterile water containing dissolved oxygen much longer than in water kept under anaerobic conditions. Thus, in one experiment, *Salm. typhi* survived in filtered tap water exposed to the air at room temperature for nearly 2 months, but died in 4 days in an atmosphere of hydrogen. They suggest that this may partly explain why this organism dies more rapidly in polluted than in pure water, and why it survives for a shorter time in summer than in winter. The importance of oxygen in favouring the growth and survival of aerobic and facultative anaerobic organisms has also been stressed by Müller (1912). Taylor (1940), on the other hand, was unable to demonstrate any close relationship between the amount of dissolved oxygen in lake water and the bacterial content; but other factors may possibly have obscured the effect.

H. Protozoal Content.—Huntemüller (1905) showed that flagellates contribute actively to the extermination of bacteria in water. River water naturally polluted by bacteria, or suspensions of *Salm. typhi*, could be cleared in 4 days if flagellates—*Bodo saltans* or *Bodo ovatus*—were added (see also Kyriasides 1931). Stokvis and Swellengrebel (1911) demonstrated a similar action by infusoria—*Colpoda cucullus*. The bacterial destruction was preceded by a rise in the number of protozoa in the water, and was probably due to active ingestion, though this was not demon-

strated conclusively. Aerobic conditions and a temperature between 10° and 30° C. were essential. König (quoted from Thresh and Beale 1925) found that in 1 ml. of water from a well at the Hygienic Institute of Munich, 21 million added typhoid bacilli perished in 24 hours. This he attributed to the action of protozoa. In pure water the death rate in this time was trifling. Increasing attention is being paid to the action of predatory plankton in the self-purification of naturally polluted waters (Butterfield *et al.* 1931, Hoskins 1935). By keeping the bacterial population below the saturation point, it is suggested that the plankton favours the continuous multiplication of bacteria in the water, which results in its turn in a progressive oxidation of organic matter.

I. Rainfall.—The effect of rainfall on the bacterial content of a water is complicated. Rain falling after a drought washes large numbers of soil organisms into the water, and hence increases the numbers of bacteria. If the rain continues for some days, relatively few organisms may be carried in during the later period of rainfall so that the stream is diluted with water purer than its own; its bacterial content therefore decreases. Again, the nature of the water is of importance. A relatively pure stream may be contaminated by rain; an impure stream may be benefited by dilution. As a rule, rivers and upland surface waters contain their greatest numbers of bacteria after heavy rainfall. In Lake Windermere Taylor (1940) observed a close association between the periodic fluctuations in bacterial content and the amount of rain that had fallen in the drainage area during the previous week.

J. Season.—The monthly variation in the bacterial content of waters depends chiefly on the temperature and the rainfall. In this country, the highest counts are generally found in the winter months, when the temperature is low and the rainfall greatest. Rivers show more variation than upland surface waters (Tables 198 and 199, pp. 2018 and 2019). The Thames in winter is swollen by heavy rain, and the quality deteriorates in consequence of the scouring effect over the whole drainage area. In summer many sources of pollution have dried up, and much of the water in the river is virtually stored or filtered water, derived from underground

TABLE 198

RAW THAMES WATER AT HAMPTON. (Houston 1913.)

Month.	Average No. of Colonies per ml. on Gelatin at 20°–22° C. in 3 days.

December	2,943	6,710	2,188

sources of supply; hence the bacterial content falls (Houston 1917). In upland surface waters, a rise in the bacterial content is not infrequent during July and August; the explanation of this is not clear, but it seems not unlikely that it is the result of dust and soil washings carried in by the summer rains (see Table 199).

December	154	39	—

In countries in which the water supply is augumented by melting snows, the bacterial content rises considerably in spring time. Oslo obtains its water supply from a lake about 160 metres above sea level. During most of the year, Schmelck (1888) found that the number of organisms per ml. was 10 to 60, rising up to 200 after heavy rain. But in the spring, when the snow was melting, the organisms increased to as many as 2,500 per ml. It is probable that this increase was due to the large amount of earth and detritus which was brought down by the glacial streams.

K. Storage.—The simple storage of water in a reservoir suffices to decrease its bacterial content enormously. Houston (1913) found that after only 15 hours' storage the New River water showed a reduction in the agar count of 40 per cent. He maintains that storage acts in three ways: (1) Sedimentation: the organisms adherent to particles of suspended matter, and those in clumps or zoogloeæ, sink to the bottom, leaving the supernatant water purer. (2) Equalization: this factor comes into play only when several waters of different qualities are collected into one reservoir. It ensures a thorough mixing of the different waters, and prevents the excess distribution of a bad supply on any one day. Even in a river, the water may not be homogeneous; samples taken from one side may be different in their bacterial content from those taken near the other side (see Table 201, p. 2021). In a reservoir, natural or artificial, homogeneity is attained. (3) Devitalization: the organisms die in large numbers, probably from lack of food supply, and ingestion by protozoa. Houston added cholera vibrios to raw river water, and found that after 1 week's storage their numbers had been reduced by 99·9 per cent.; after 3 weeks they could not be isolated even from 100 ml. of water. Table 200 shows the effect of storage on the London water.

TABLE 200

EFFECT OF STORAGE. 1907–08. AVERAGE RESULTS. (Houston 1913.)
Bacteria per ml.

	Gelatin, 20°–22° C.	Agar, 37°C.	No. of Samples with *Bact. coli* in 0·01 ml.
River Thames before storage	4,465	280	10·1%
River Thames after 15 days' storage at Chelsea	208	44	1·1%
Reduction	95·3%	84·3%	89·1%

The reduction occurs not only in pathogenic organisms and *Bact. coli*, but in organisms of all sorts, though not always equally. Houston states that even 1 week's storage would be more efficacious, in reducing the initial numbers of typhoid bacilli or cholera vibrios in a water, than sand filtration.

It is probably owing to storage that lake waters are so much purer than the streams that feed them. Some rivers with a very low gradient may offer conditions suitable for sedimentation.

L. Filtration.—Natural filtration occurs on a large scale, resulting in the accumulation of the underground deposits of water that are tapped by deep wells and main springs. Its efficacy in the removal of bacteria depends on the nature of the soil, and the depth of the strata penetrated. In loose, porous soils a greater depth must be traversed to ensure the same degree of purification that is attained by filtration through a more compact soil. Evidence suggests that, in a soil of moderate density, the greater part of the bacteria are removed in the first 10 or 15 feet. This is the reason why deep well water is so pure.

Artificially, sand filtration is used to remove bacteria from water in order to render it potable. Houston (1913) finds that this process, which in the case of the London waters follows storage for 30 days, removes 98 per cent. of the residual bacteria.

M. Other Factors.—It is known that certain rivers have a bactericidal effect on some of the intestinal organisms. Thus Arloing and Sempé (1924) state that the water of the Saône inhibits the growth of *Bact. coli* but not of *Salm. typhi*. The water of the Isère inhibits the growth of *Salm. paratyphi A*; the Rhône *Salm. typhi*; and the sea at Havre *Shigella shigæ* (Arloing and Chavanne 1925, Arloing and Sempé 1926). In India the water of the Ganges is said to destroy the cholera vibrio (see Khan 1930). Arloing and Sempé (1926) and Bujanowski (1929) have advanced some evidence to suggest that this inhibitory, and often highly specific action, is dependent on the presence in the water of a transmissible lytic agent, similar to that described by Twort and by d'Herelle. If this work is confirmed, it will be an interesting addition to our knowledge of the means by which waters undergo natural purification; and it may serve to explain why certain regions are relatively immune to water-borne diseases—though this seems unlikely.

Self-Purification of Rivers.

From what has already been said, it is clear that the number of bacteria in a particular sample of water is determined by several factors, the precise effect of which it is difficult to assess. It is also clear that such factors as absence of organic matter, the presence of numerous protozoa, a high acidity, and the opportunity

for sedimentation, are able to bring about a considerable reduction in the bacterial flora. It is not surprising, therefore, that rivers that have been heavily polluted by sewage may regain their natural purity after flowing for some distance. Jordan's (1900) observations on the Illinois river are of interest. The portion of the river that he examined was between Morris and Ottawa. Nine miles above Morris two tributaries unite, the relatively pure Kankakee, and the Desplaines, laden with Chicago sewage. During its flow of 24 miles from Morris to Ottawa the river improved in purity in spite of the absence of dilution with fresh water. The observations were made in October and November when there was neither sun nor rain (Table 201).

TABLE 201

	Distance from Morris.	No. of Colonies per ml.			No. of Hourly Analyses.
		Right Bank.	Middle.	Left Bank.	
Upper station, Morris .	—	261,000	204,000	29,000	3
Middle station, Seneca .	12 miles (24 hours)	100,000	49,000	35,000	2
Lower station, Ottawa .	24 miles (48 hours)	11,500	10,700	13,500	2

The extraordinary degree of purification that occurred was accounted for partly by the slow movement of the river, which permitted sedimentation to occur, and partly by the absence of sufficient food-supply to support the large number of contaminating organisms. Jordan found between Morris and Ottawa a decrease in the albuminoid ammonia of 0·382 to 0·049 parts per million, and in the oxygen consumed of 2·3 to 2. This diminution was probably due to bacterial action.

There is no space to discuss more fully the self-purification of rivers. Enough has been said to indicate the most important factors controlling it. Moreover the importance of each factor varies with different rivers. The reader is referred to a study of the self-purification of the Spree below Berlin by Frank (1888), of the Danube below Vienna by Brezina (1906), and of the Whangpoo by Hamilton (1935).

Bacteriological Analysis

We do not propose to give a detailed description of the bacteriological analysis of water, since the Ministry of Health (Report 1939*a*) in this country and the American Public Health Association (1936*b*) in the United States have each described standard methods for its performance, to which reference should be made by those desirous of further knowledge. Great attention has to be paid to the sampling of the water (for details see Report 1939*a*), and to the technical performance of the various procedures involved (for error of these see Wilson *et al.* 1935).

Plate Count.—In general, the analysis consists in an enumeration of the organisms or groups of organisms capable of forming colonies on a standard nutrient agar medium incubated aerobically at 20°–22° C. for 3 days or at 37° C. for 2 days. Since not all the organisms in water are viable ; since many viable organisms, such as those of the anaerobic and nitrifying groups, do not develop under the particular conditions provided ; and since some of the organisms occur in groups which give rise only to a single colony—it is clear that the colony count corresponds not to the total number of organisms or even to the number of viable organisms, but only

to the number of bacterial units that are able to multiply under the nutritional, respiratory, and temperature conditions supplied. For this reason it should be reported either as the " number of colonies developing per ml.," or more simply as the " plate count per ml."

Coliform Count.—Besides a general bacterial enumeration, an attempt is made to estimate the number of coliform bacteria in the water, and often to ascertain the proportions of the various types of these organisms. The ideal method of doing this would be a direct plate count on a differential medium. So far, however, no medium has been devised that will differentiate with certainty between coliform and non-coliform organisms, or between the different types of coliform bacilli. Partial success in these respects has been claimed by Tonney and Noble (1930, 1931*a*, *b*, 1932*a*, *b*) for their ferrocyanide citrate agar medium, by Gehm and Heukelekian (1935) for eosin methylene blue agar, and by Littman and Stark (1938) for citrate ricinoleate agar.

The usual technique for estimating coliform bacilli is by the dilution method in a liquid medium, which allows the observation of gas production—an important property serving to distinguish coliform from most non-coliform bacilli. As has already been pointed out (Chapter 4), the dilution method is subject to a big sampling error. The results depend not only on the number of dilutions prepared and on the number of tubes of each dilution inoculated, but also on the number of organisms present in each unit volume of the original water. Hence attempts have been made to devise the most economical method of carrying out the examination consistent with reasonable accuracy (Halvorson and Ziegler 1933*a*, *b*, Swaroop 1940, 1941). Even greater effort has been expended in endeavouring to convert the results obtained into terms of the probable number of organisms present (see Greenwood and Yule 1917, McCrady 1918, Hoskins 1934, Matuszewski and Supińska 1937, Haldane 1939, Pomeroy 1940, Buchanan-Wollaston 1941). No perfect medium has yet been devised that will enable all coliform organisms to develop and produce gas, while suppressing the growth, or at least the gas formation, of other organisms.

British practice favours MacConkey's bile salt lactose medium, but in the United States other media, such as lactose broth (Report 1936*b*), brilliant green lactose bile broth (Jordan 1927), fuchsin lactose broth (Ritter 1932, 1938), methylene blue brom cresol purple broth (Dominick and Lauter 1929), crystal violet lactose broth (Salle 1930), formate ricinoleate broth (Stark and England 1935), gentian violet lactose bile broth (Kessler and Swenarton 1927), the so-called " E.C. " medium (Perry and Hajna 1944), and lauryl sulphate tryptose broth (Mallmann and Darby 1941), have been recommended. It is impossible to say which of these media is the best, since reports on comparative trials are at variance (see Shunk 1935, Raghavachari and Iyer 1936, Farrell 1937, Atkinson and Wood 1938*a*). The results may well depend on the bacterial flora of the water under examination. Generally speaking, there is an advantage in not having to depend on dyes to suppress the growth of non-coliform organisms, since standardization of the medium is difficult to achieve.

In this country a series of MacConkey broths are inoculated with falling quantities of water, namely one 50 ml. quantity, five 10 ml., five 1 ml., and, if necessary, five 0·1 ml. quantities, incubated at 37° C. for 2 days, and the number of tubes showing acid and gas noted. The results are reported in terms of the probable numbers of coliform bacilli per 100 ml. (see Report 1939*a*). Since acid and gas production may be due to certain aerobic spore-bearers (see Greer 1928, Porter *et al.*

1935), or to the synergic action of two different types of bacteria, one of which attacks lactose and the other of which produces acid and gas from the glucose so formed (see Atkinson and Wood 1938*b*), the count is best referred to as the "presumptive coliform count." In Great Britain, where MacConkey broth is used, false positive results from these causes are uncommon in water examination (see Bardsley 1938*a*); but in the United States, where lactose broth free from bile salt is the standard medium, a varying proportion of the presumptive positive tests are not "confirmed" on further investigation.

Differential Coliform Count.—Not infrequently it is desirable to ascertain the types of coliform organisms present. For this purpose it is usual to plate out on to MacConkey agar two or three of the positive tubes inoculated with the smallest quantities of water, to incubate for 24 hours, to pick off 2 or 3 lactose-fermenting colonies from each plate, and to test these in a series of media capable of differentiating between organisms of the coli, intermediate, and aerogenes-cloacæ types (see Chapter 28). This method, besides being tedious, suffers from two main objections. Firstly, if one type of organism is present in the original water in much smaller numbers than another type, it is liable to be diluted out during the preparation of the dilutions, so that plates inoculated from the positive tubes seeded with the smallest quantities of water will yield a culture of the commoner organism only. Secondly, even if the two types are present in approximately equal numbers, one type is liable to outgrow the other, so that again a pure, or almost pure, culture of one type develops on plating.

To obviate these errors, a method has been suggested (Wilson *et al.* 1935) which consists in subculturing *all* MacConkey broths showing acid and gas (1) into a fresh series of MacConkey broths, which are incubated at 43°–45° C. in a water-bath, and (2) into tubes of Koser's citrate, which are incubated at 37° C. The production of gas in MacConkey broth—but not necessarily in other media—at 44° C. seems to be characteristic of *Bact. coli* of fæcal origin, while the ability to grow in Koser's citrate is distinctive, in the coliform group, of the intermediate and aerogenes-cloacæ types. By making use of probability tables it is thus possible to obtain within 3 or 4 days a quantitative estimate of the organisms belonging to the coliform, the fæcal coli, and the intermediate-aerogenes-cloacæ groups. In this method, though the different types may be present in very unequal proportions in the fermented tubes, transference to selective liquid media will enable growth of even minimal numbers to occur.

The value of the 44° C. MacConkey test for picking out *Bact. coli* of fæcal origin has now been abundantly confirmed (see p. 664); though in Madras and Singapore some strains of *aerogenes* type have been found capable of producing gas at this temperature (Raghavachari and Iyer 1939*a*, Boizot 1941). The citrate test is less specific for members of the intermediate-aerogenes-cloacæ group when used for direct inoculation from a fermented 37° C. MacConkey broth culture, owing to the ability of some late-lactose and non-lactose fermenters and even *Bact. coli* to grow in this medium (see Bardsley 1938*a*, Raven *et al.* 1940, Ferramola 1940). In practice, however, this is not usually a serious drawback, since most false positives in citrate occur with the more polluted waters, which would be condemned in any case on the presumptive coliform or the fæcal coli count.

The selective liquid media method has now been adopted officially by the Ministry of Health (Report 1939*a*) for the differential coliform test in the bacteriological examination of waters. In the extensive trials during the second world

war, it proved to be reliable, and to be economical in both time and medium. The specificity of the 44° C. MacConkey test for *Bact. coli* in this country has only once been questioned (Harding 1940), and on investigation the criticism proved to be unfounded. It may, however, be noted that Taylor (1945), working in a particular locality, has reported gas production in MacConkey's medium at 44° C. by as many as 15 per cent. of *Bact. aerogenes* strains.

Classification of Coliform Organisms in Water.—In Chapter 28 we have discussed the classification of lactose-fermenting coliform bacilli according to the general principles of systematic bacteriology. In water analysis it is of greater advantage to classify these organisms in relation to their habitat, paying particular attention to their excretal or non-excretal origin. Such a classification is given in Table 202.

TABLE 202

CLASSIFICATION OF COLIFORM STRAINS MET WITH IN GREAT BRITAIN

Type.	M.R.	V.P.	Growth in Citrate	Indole.	Gas in MacConkey at 44° C.	Gelatin Liquefaction, 7 days.	Probable Habitat.
Bact. coli, Type I, fæcal	+	−	−	+	+	−	Human and animal intestine.
Bact. coli, Type II. .	+	−	−	−	−	−	Doubtful; possibly partly intestinal.
Intermediate, Type I .	+	−	+	−	−	−	Mainly soil.
Intermediate, Type II	+	−	+	+	−	−	Mainly soil.
Bact. aerogenes, Type I	−	+	+	−	−	−	Mainly vegetation.
Bact. aerogenes, Type II	−	+	+	+	−	−	Mainly vegetation.
Bact. cloacæ . . .	−	+	+	−	−	+	Mainly vegetation.
Irregular, Type I . .	+	−	−	+	−	−	Human and animal intestine.
Irregular, Type II. .	+	−	−	−	+	−	Doubtful.
Irregular, other types	Reactions variable.						Doubtful.

It will be seen that *Bact. coli* Type I, Irregular Type I, and possibly some of *Bact. coli* Type II (see Bardsley 1938*a*, Stuart *et al.*, 1942) appear to find their natural habitat in the mammalian intestine. It is true that strains belonging to the intermediate-aerogenes-cloacæ (I.A.C.) group are often found in fæces, but as a rule they are present in only very small numbers. Their natural habitat is still unknown (see Taylor 1942*a*), but the great mass of evidence suggests that it is not primarily intestinal. Since Irregular Type II, which produces gas in MacConkey at 44° C., is very uncommon in fæces, it follows that a positive 44° C.

MacConkey test is practically diagnostic of fæcal coli. The fact that neither *Bact. coli* Type II nor Irregular Type I produces gas in MacConkey at 44° C. is of little practical importance, since these organisms constitute only a very small proportion of the fæcal coliform flora (Bardsley 1938*a*).

Examination for Fæcal Streptococci, Cl. welchii, and Pathogenic Organisms.—The plate and coliform counts constitute the usual water analysis. Sometimes, however, further information is required, and search may have to be made for special organisms.

In examining water for fæcal streptococci advantage is taken of the partial heat resistance of these organisms, and of their ability to form acid in MacConkey's medium and to grow in the presence of a concentration of potassium tellurite sufficient to prove inhibitory to most coliform organisms (see Report 1939*a*).

The search for *Cl. welchii* is conducted either by anaerobic incubation of litmus milk after preliminary heating to 80° C. for 10 minutes to destroy non-sporing organisms, or by use of W. J. Wilson's (1928) glucose sulphite iron agar medium.

Typhoid and paratyphoid bacilli are difficult to demonstrate in water, partly because of technical difficulties, and partly because, unless the contamination of the water is continual, these organisms will have died out by the time suspicion of their presence is aroused. Far and away the most satisfactory method is the use of the bismuth sulphite brilliant green medium devised by W. J. Wilson and Blair (1931) (see also W. J. Wilson 1938). When the difficulties of making this medium have been overcome, the results are highly successful, and typhoid and paratyphoid bacilli can be isolated even from crude sewage (see Houston 1930).

In the demonstration of *V. cholerœ* advantage may be taken of its rapid growth in alkaline peptone water under aerobic conditions, and of the various differential media available (see Chapters 22 and 63).

Interpretation of the Bacteriological Analysis.—Before attempting to give an opinion on the results of a bacteriological analysis, it is essential to gather particulars of the nature of the water, the method by which it was collected, the time of collection, and the amount of recent rainfall. It is sound practice, though not always possible, for the bacteriologist to make a topographical survey of the gathering ground, so as to ascertain the extent and the kind of pollution to which it is subject. If he is unable to do this personally, he should consult a map in which the source of the water and the immediate environment are indicated. Particular care must be given to the mode of collection of the sample; otherwise contamination, especially with coliform organisms, may disturb the interpretation of the results (for instructions, see Report 1939*a*).

The whole aim of the bacteriological analysis of water is to find evidence of excretal pollution. Since we can rarely isolate directly specific pathogenic organisms, such as *Salm. typhi*, we resort to estimating first of all the number of living bacteria of all sorts in the water, and secondly the number of living bacteria of intestinal origin. The greater the number of bacteria, the greater, presumably, is the amount of decomposing organic matter. The more bacteria of intestinal origin there are, the more likely are pathogenic species to be amongst them. Our evidence therefore is circumstantial, and is frequently open to doubt in its interpretation.

Unfortunately we cannot lay down absolute standards for all waters; but we can lay down a standard for any one water. This is possible by frequent and regularly repeated examinations, which teach us the range of normal variation.

We become acquainted, in fact, with the bacterial character of the water. Any marked deviation from the norm is at once regarded with suspicion. On a water which we examine for the first time and for which we have no absolute standards, it is often difficult to express more than a tentative opinion. A high agar count at 22° C., for example, may be significant or it may not; and though the sanitary survey may assist us on this point, it may not be till several examinations under different conditions have been made that we can offer a definite opinion.

The agar count at 22° C. gives us information on the amount of decomposing organic matter in the water available for bacterial nutrition. Most bacteria that develop at 20° C. are non-pathogenic to human beings, and it might therefore be thought that their number was immaterial. On the other hand they afford some indication of the amount of extraneous organic matter available for bacterial nutrition that has gained access to the water from various sources. On general grounds the greater the amount of organic matter present, the more likely is the water to be contaminated with parasitic and potentially pathogenic organisms. Occasionally in unpolluted deep well waters there may be a high agar count at 22° C., running into thousands or tens of thousands per ml. This is found, as a rule, to result from the presence of a single species of organism that has apparently gained access from the air and multiplied abundantly. The colonies develop slowly and are often chromogenic. Such a finding can usually be ignored

The agar count at 37° C. is a more important index of dangerous pollution. Most of the natural and harmless bacteria in water do not grow readily at 37° C.; the organisms developing at this temperature are chiefly of soil, sewage, or intestinal origin. Hence our standards must be more stringent than at 22° C. A high 37° C. agar count is often sufficient to condemn a water, though there are a number of exceptions to this rule. For example, recently sunk wells and bores are liable for some time to give an unduly high count, which later decreases as the well settles. In upland surface waters the 37° C. agar count may be very high, sometimes exceeding 1,000 per ml., even in the absence of excretal pollution. During the summer months the count may rise in such waters, owing partly tothe access, of dust and organic matter to the water, and partly to the increase in te mperature both of which favour bacterial multiplication. Waters stored under certain conditions, as in metal tanks, may have a 37° C. agar count in the thousands, though no coliform bacilli may be demonstrable. The 37° C. agar count is of particular value in the control of filtration. With slow sand filters the count on the filtered water should show a 95–98 per cent. reduction on that of the raw water. A rise in the colony count is the usual signal of defect in the filter beds, demanding instant attention.

It is generally found that in a pure water about ten times as many organisms develop at 22° C. as at 37° C.; in a polluted water this ratio is often less. Some workers place more weight on the value of this ratio than on the individual counts. This, we consider, is a mistake. The ratio may vary within wide limits, quite independently of the amount of fæcal contamination. Table 203 brings out this point. Moreover, in a water treated with chlorine, the number of colonies at 22° C. and 37° C. may be almost equal. This is doubtless accounted for by the susceptibility of the natural water bacteria, and the resistance of the spore-bearing soil bacteria; both counts are lowered absolutely, but the 22° C. far more than the 37° C.

Just as the 37° C. is of greater significance than the 22° C. agar count, so the number of coliform bacilli is a more reliable index of excretal pollution than the

37° C. plate count. It is also easier to lay down an absolute standard for *Bact. coli* than for either of the other two counts. For example, this organism should not exceed 1 per 100 ml. in deep well water, or 5 per 100 ml. in a shallow well or upland surface water. Its presence in greater numbers is strongly suggestive of pollution.

TABLE 203

Modified from Thresh and Beale (1925).

Source of Water.	Colonies per ml.		Ratio of Gelatin to Agar.
	Gelatin 20° C.	Agar 37° C.	
Unpolluted deep well in chalk	61	3	20 : 1
Do.	161	13	12 : 1
Do.	9	3	3 : 1
Unpolluted spring water	51	3	17 : 1
Do.	34	6	6 : 1
Polluted deep well in chalk	84	4	21 : 1
Do.	260	72	4 : 1
Polluted shallow well	1,560	38	41 : 1
Do.	151	4	36 : 1
Polluted river water	6,300	140	45 : 1
Do.	29,600	3,300	9 : 1

A distinction should be drawn between the typical coli I, which is usually of excretal origin, and the other types of coliform bacilli, which are more often derived from other sources (see Table 202). There is no question that coli I—the fæcal coli type—is the most delicate index we have of recent excretal pollution. With regard to the importance of the intermediate and aerogenes-cloacæ types (I.A.C.) opinion is divided. There are those who maintain that, because these organisms are found in fæces—though only in small numbers—their presence cannot be neglected. There are those who draw attention to the fact that organisms of the aerogenes type are often present in infected urine (Hill *et al.* 1929, Burke-Gaffney 1933), and may constitute the dominant type of coliform bacilli in human fæces (Parr 1936). There are others who point out that, if recent excretal pollution has occurred, fæcal coli will undoubtedly be found too, so that the presence of other types in the absence of fæcal coli can generally be ignored.

The interpretation is to some extent affected by the rate at which these different organisms die out after gaining access to water. Here again our data do not provide us with a clear answer.

The vitality of these organisms in water varies with several factors. Houston (1913) found that storage of water for 15 days reduced the number of *Bact. coli* by 80–90 per cent. Gray (1932) and Burke-Gaffney (1933) bring evidence to show that *Bact. coli* dies out more rapidly than *Bact. aerogenes*. Ruchhoft and his colleagues (1933) find that both organisms disappear at about the same rate. Platt (1935) finds that this rate depends to some extent on the temperature, *Bact. aerogenes* surviving longer than *Bact. coli* at 18°–20° C., but not at 0° C. or 37° C. Raghavachari and Iyer (1939*b*) suspend their judgment. Hamilton (1935), in China, finds that in the summer months *Bact. aerogenes* may actually multiply in water under favourable conditions.

On the whole, the evidence suggests that organisms of the I.A.C. group tend to be rather more resistant to environmental conditions than fæcal coli. Their presence in water, in the absence of fæcal coli, may indicate either (1) that non-

polluted dust or soil has gained access to the water; or (2) that excretal contamination has occurred at a time sufficiently remote to permit the disappearance of all fæcal coli organisms; or (3) that the water is subject to a minor degree of excretal contamination heralded, for some reason which is not yet clear, by the appearance of organisms of the I.A.C. group before true fæcal coli; or (4) that a contaminated water has been insufficiently chlorinated; or (5) that the water—and this applies to wells and pumps—is being contaminated from such material as old sacking, leather washers, jute packing, or decaying leaves, in which organisms of the I.A.C. type are actively growing. Which of these explanations is correct, it is usually impossible to say on any one sample of water without further examination.

In this country a high proportion of waters giving a positive presumptive coliform test contain fæcal coli (Bardsley 1934, 1938*a*), and it is therefore often unnecessary to proceed to a differentiation of the coliform types. In the routine control of water supplies from which coliform bacilli are usually absent, the appearance of these organisms demands immediate attention, and differentiation should be carried out in order to obtain a clue to the probable source of pollution. Differentiation is likewise called for when a new supply is under examination, as it is always desirable to learn as much as possible about the flora normally present. In other types of water differentiation is a matter for individual judgment. Generally speaking, there is little point in determining the nature of the types present in a piped water supply if the presumptive coliform count exceeds about 10 per 100 ml., since even if no fæcal coli are found the water will still have to be regarded as probably contaminated. In shallow well waters, however, differentiation may be useful with a coliform count up to about 50 per 100 ml., as the degree of excretal pollution may be so small as to render it unnecessary to condemn the water when, as usually happens, it is being consumed by only a small number of persons. Unfortunately, there is no reliable method of distinguishing coliform organisms of human and animal origin.

In the *tropics* a fairly high proportion of coliform organisms in water are often found to be of the intermediate or aerogenes-cloacæ types. Since careful sanitary surveys have shown that such waters may be free from exposure to excretal contamination, it is clear that reliance on the presumptive coliform count in the tropics will result in the unnecessary condemnation of a number of unpolluted waters. Differentiation will generally be necessary, and attention should be devoted mainly to the numbers of fæcal coli.

In cases where the probable origin of coliform bacilli is doubtful, use may be made of the tests for fæcal streptococci and *Cl. welchii*. Both of these organisms are commonly present in mammalian fæces. If they are found in significant numbers in the water, they may be regarded as indicating that the doubtful coliform bacilli were probably of excretal origin. Their absence, on the contrary, points to the reverse conclusion. It is mainly as an aid to the interpretation of the coliform result that a test for these organisms finds its real value. It must be pointed out, however, that both fæcal streptococci and *Cl. welchii* probably survive longer in water than fæcal coli, so that their presence in the absence of this organism is generally indicative of remote rather than of recent excretal contamination. (For further information on the coliform group of organisms in relation to water supply in the tropics reference should be made to papers by Pawan 1925, 1926, 1931, Raghavachari 1926, Raghavachari and Iyer 1939*a*, *b*, Hicks 1927, Taylor 1927, and Burke-Gaffney 1932, 1933.)

Standards.—It will be obvious that the larger the population is to which the water is distributed, the more stringent must our standards be. The occurrence of typhoid fever in the inmates of a cottage drawing water from a polluted well is unfortunate, but its occurrence in the population of a large town is a catastrophe. The standards that we give here are those suggested by the Ministry of Health (Report 1939*a*), and refer only to piped water supplies. As will be seen, they are based entirely on the results of the coliform test, since this affords the most delicate, the most specific, and at the same time the most generally applicable index of pollution.

Non-chlorinated Piped Water Supplies

		Presumptive Coliform Count per 100 ml.
Class 1.	Highly satisfactory	less than 1
Class 2.	Satisfactory	1–2
Class 3.	Suspicious	3–10
Class 4.	Unsatisfactory	Greater than 10

Owing to the large sampling error of the coliform count, too much attention should not be paid to minor fluctuations in these figures. For this reason the Ministry proposes that throughout the year 50 per cent. of samples should fall into Class 1; that 80 per cent. should not fall below Class 2; and that the remainder should not fall below Class 3. Chlorinated waters ought uniformly to come into Class 1.

For the student's guidance we give two examples of unpiped and unpurified waters destined for consumption by a small population. Though the deep well and main spring water would be safe for a town supply, the second water we quote would have to be purified before its delivery to a large number of consumers would be justified.

Deep Well and Main Spring Waters

Plate count, agar 3 days at 22° C.	10–200 per ml.
Plate count, agar 2 days at 37° C.	1–10 per ml.
Bact. coli fæcal Type I	Less than 1 per 100 ml.
Fæcal streptococci	Less than 1 per 100 ml.
Cl. welchii	Less than 1 per 1,000 ml.

Shallow Well, Land Spring, and Upland Surface Waters

Plate count, agar 3 days at 22° C.	50–500 per ml.
Plate count, agar 2 days at 37° C.	5–30 per ml.
Bact. coli fæcal Type I	Less than 5 per 100 ml.
Fæcal streptococci	Less than 5 per 100 ml.
Cl. welchii	Less than 5 per 1,000 ml.

A filtered river water should conform to the standard of a good shallow well water. If chlorination has been used in addition, then the coli standard should equal that of a deep well water.

The effect of rainfall on the water should be noted carefully. Speaking generally, the less the water is influenced by this factor the better. Though rain in itself contains relatively few bacteria, it may carry in large numbers of undesirable organisms from the soil. A large increase in the number of organisms, especially if attended by a rise in the coli count, should always be regarded with suspicion.

There is often a tendency for more weight to be placed on the results of the

bacteriological examination than is justifiable. If the sanitary survey shows the water to be clearly subject to human excretal pollution, then it is not exaggerating to say that a bacteriological examination is redundant. Even should a reasonably good result be obtained on one sample, there is no doubt that repetition on further samples, taken perhaps after heavy rainfall, will reveal the presence of coliform bacilli in large numbers. Bacteriological examination is a delicate tool suitable for revealing pollution too small in amount or too obscure to be noticeable by the ordinary means of the topographical survey. If the relatively crude method of the survey shows the presence of undoubted contamination, then the delicate methods employed by the bacteriologist are seldom required. It follows that no water exposed to known contamination should ever be reported on favourably by the bacteriologist, regardless of what the laboratory findings may be.

Finally we repeat that judgment on the potability of a water can be given only after a careful weighing of all the evidence available. It must be remembered that the mere absence of evidence indicating fæcal pollution does not necessarily indicate that pollution has not taken place. All it does show is that at the time the sample was examined, there was no detectable evidence of pollution. It is partly for this reason that frequent examinations are desirable.

The interpretation of the bacteriological analysis, particularly on a new supply, is greatly facilitated by a concurrent chemical analysis, which furnishes information on the amount of organic matter in the water. The results obtained by the two methods of examination should be carefully correlated. As a rule, they are in substantial agreement, but discrepancies are occasionally found which show the need for caution in the report, and perhaps for the desirability of a further examnation.

Swimming Bath Waters.—The main organisms found in swimming bath water are aerobic spore-bearers, *Pseudomonas*, *Chromobacterium*, coliform bacilli, *Proteus*, staphylococci of skin and salivary origin, streptococci, *Neisseria*, and *Cl. welchii*. According to Bardsley (1938*b*) most of the coliform bacilli are of excretal origin and consist chiefly of organisms of the coli I type; but members of the I.A.C. group are also present, and in chlorinated waters may actually exceed coli I in number. A little reflection will enable the student to understand why the bacteriological control of swimming bath waters is unsatisfactory. The results vary from one part of the bath to another, and from minute to minute in the same part depending on the numbers and personal cleanliness of the bathers. Though the addition of chlorine to the water to give a residual figure of 0·2–0·5 parts per million should result in a sterile 37° C. agar plate count and in the absence of coliform organisms from 50 ml. of the incoming water (Report 1929), it is impossible to maintain virtual sterility in the bath itself without adding chlorine in such excess as to cause severe irritation to the nasal and conjunctival mucosa of the bathers. Infection, either of nasopharyngeal or of excretal origin, may pass from one person to another with great rapidity, so that no bearable chlorine concentration can be expected to destroy the organisms concerned. In practice it is wise to examine the in-flowing and the out-flowing water, if continuous circulation is being maintained. The standard of the in-flowing water should be that quoted above. For the out-flowing water no standard can be laid down, but if the 37° C. agar plate count exceeds 200 per ml., and the presumptive coliform count exceeds 2 per 100 ml., steps should be taken for more rapid circulation of the water, or for a higher residual chlorine concentration in the water entering the bath.

Water-borne Disease.—The main diseases carried by water are enteric fever, dysentery, and cholera. For a description of these reference should be made to Chapters 63, 69, 70. In this country the incidence of water-borne disease is low compared with some parts of the Continent and with the United States, but is by no means negligible. Between 1911 and 1937 there occurred in England and Wales at least 21 outbreaks of disease conveyed by public water supplies, resulting in 1,237 cases of enteric fever, 2,800 of bacillary dysentery, and 7,439 of gastro-enteritis (Report 1939*b*). In the United States, Gorman and Wolman (1939) were able to collect records of 399 outbreaks during the period 1920 to 1936, affecting 115,645 persons. Among the cases of disease were 12,585 of typhoid fever and 101,603 of diarrhœa. It may be noted that paratyphoid fevers are seldom water-borne. Franklin and Halliday (1937) report one outbreak of paratyphoid A fever in Canada due to contamination of a well water from a resident who had returned to her home suffering from an undiagnosed disease; and there have been 2 or 3 small outbreaks of paratyphoid B fever in this country (see Report 1942, Page 1942). As is apparent from the records just given, diarrhœa and gastro-enteritis figure prominently in water-borne disease. Their nature and causation are not always clear. Some outbreaks may be due to undetected dysentery bacilli, but there seems little doubt that the access of sewage in considerable amount to a water supply may be followed by gastro-enteritis in the absence of any recognized pathogenic organisms (see Kathe and Königshaus 1932, Report 1936*a*, 1937, Pharris *et al.* 1938). Lead poisoning has, of course, to be borne in mind, as well as less common forms of chemical poisoning, such as that described by Campbell (1940) of naphthalene poisoning following the painting of a storage tank.

Infection of the water may occur at the source, during storage, or during distribution. The prevention of water-borne disease demands scrupulous care and supervision of every part of the system, including the health of operatives closely associated with the water itself (see Report 1939*b*).

SHELL FISH

The chief importance of shell fish from a public health point of view is their liability to give rise to enteric fever. In France alone it is estimated that within a period of 15 years more than 100,000 cases of typhoid fever due to the consumption of shell fish occurred, of which 25,000 ended fatally (Belin 1934).

Shell fish become infected by being laid down in polluted water. According to Eyre (1924), about 2 litres of water enter and leave the shell of an oyster every hour. Large volumes of water also pass through mussels every 24 hours. The bacterial flora of these shell fish is largely determined by the nature of the water in which they are immersed. This is often subject to rapid changes. It is quite possible, for example, for mussels to be heavily polluted on an ebb tide and to clean themselves on a flood tide. The only satisfactory way of ensuring their purity is to lay them down for some days in non-polluted, preferably chlorinated, water (see Dodgson 1936).

An attempt is often made to control the suitability of shell fish for human consumption by bacteriological methods. The general principles of such an analysis are similar to those we have just discussed in the examination of water, particular

attention being paid to the numbers of coliform bacilli. The difficulties, however, of obtaining an exact bacterial enumeration are considerably greater with shell fish than with water. The chief reason for this is the extraordinary variation in numbers from one oyster or mussel to another, and the gross irregularity in distribution of organisms within the individual shell fish themselves. There is in this country no standard method of analysis or standard of interpretation laid down for the examination of shell fish, with the result that many workers have evolved their own technique. Since the methods of different workers often differ in major points, we shall refrain from describing any one in detail. Those who are interested may be referred to papers by Eyre (1924, 1933), Dodgson (1928, 1936, 1938), Perry (1928, 1929), Bigger (1934), Beard and Meadowcroft (1935).

The standard adopted by the Fishmongers' Company in this country, based on the recommendations of Andrewes, Hewlett and Eyre (1924), allows approximately 100 coliform bacilli per oyster in 40 per cent. of the oysters sampled. For purified oysters Dodgson (1938) exacts a more rigid standard, namely not more than 50 coliform bacilli in any oyster. The presumptive coliform test, however, may be grossly misleading, as organisms of the aerogenes-cloacæ type may, under favourable conditions, multiply enormously in mussels, barnacles, raw sea water, and sterilized tank water. This difficulty may be overcome by using the 44° C. MacConkey broth test for fæcal coli (Dodgson 1938). Just as with water, so in the control of shell fish, a careful topographical survey to exclude possible sources of pollution is essential; bacteriological examination must remain as an ancillary method to check the results of the sanitary investigation.

SEWAGE

In this country crude sewage contains about 10 million organisms per ml. capable of developing on gelatin at 20° C., and from 1 to 5 million per ml. on agar at 37° C. In America the numbers appear to be lower. There is often a marked rise in the summer months. The organisms making up these numbers are of many different kinds, and vary from one sewage to another. Prominent amongst them are the *Proteus* group, the coliform bacilli, streptococci, anaerobic spore-bearing bacilli, natural water bacteria, and the denitrifying bacilli. *Bact. coli* may number 100,000 per ml., *Streptococcus fæcalis* 1,000 to 10,000 per ml., and *Cl. welchii* 100 to 1,000 per ml. Pathogenic organisms of the typhoid, paratyphoid, and food-poisoning groups can often be found in crude sewage by the use of appropriate selective media. The poliomyelitis virus has also been demonstrated in it (Paul and Trask 1941, 1942). Sewage is an excellent source of a large variety of bacteriophages.

The process of purification is accompanied not so much by a diminution in the numbers of organisms, as by a change in the distribution of different organisms. Thus in the septic tank, the anaerobic liquefying bacteria are prominent; on the contact beds the aerobic liquefying and the denitrifying bacteria gain the upper hand. It is evident that enormous numbers of bacteria must perish in the process; by a comparison of the microscopic and the gelatin counts, Winslow (1905) found that the ratio of the total to viable organisms was about 20 to 1 in crude sewage, 40 to 1 in the septic tanks and filter beds, and 70 to 1 in the sand filter effluents. Table 204 illustrates the numerical changes occurring during biological purification.

TABLE 204

BOSTON SEWAGE. (Modified from Winslow 1905.)

	Microscopic Count.	Gelatin.	Agar.	Microscopic ÷ Gelatin.	Agar × 100 ÷ Gelatin.
Crude sewage . .	29,000,000	1,690,000	1,400,000	17	83
Septic tanks . .	30,000,000	787,000	504,000	38	64
Contact filters .	24,000,000	521,000	432,000	46	83
Trickling filters .	17,000,000	451,000	284,000	39	63
Sand filters . .	65,000	9,160	10,800	7	120

It will be seen that no marked fall occurs in the number of living organisms till the sand filter stage is reached.

A method of sewage disposal that is now widely used is the Activated Sludge Process. Briefly this consists in treating the sewage with about 15 per cent. of bacterially active liquid sludge, in the presence of an ample supply of atmospheric oxygen. As a result of this treatment, a large proportion of the colloidal material undergoes coagulation, and subsequent sedimentation. The activated sludge itself results from the aeration of successive portions of sewage (see Martin 1927, Buswell 1928). As Wooldridge and Standfast (1936) have shown, the purification is brought about by a series of catalysed oxidation-reduction reactions determined by bacterial enzymes present in the living or dead bacterial cells or liberated by them into the fluid of the reacting system. A reduction of as much as 98 per cent. in the number of living bacteria may occur during the process (Miller 1936).

The survival of typhoid bacilli in sewage has been studied by a number of workers (see Green and Beard 1938). The rate at which they die out depends on a variety of factors. As a rule, the great majority are dead within a week and all within a month. Their death is probably accelerated by the activated sludge process of treatment, though observations on *Salm. typhi-murium* have shown that this organism may survive in drying sewage sludge for several months (Stokes *et al.* 1945).

CHAPTER 93

THE BACTERIOLOGY OF MILK

Sources of Bacteria in Milk

EVEN when drawn with aseptic precautions, milk always contains a certain number of bacteria which are derived from the milk ducts of the **cow's udder.** Their numbers vary considerably from quarter to quarter and from cow to cow, and are highest in the fore-milk and lowest in the strippings. The average plate count of aseptically drawn milk has been given by different workers as less than 10 per ml. to several thousand. Many of the lower counts have probably underestimated the true number owing to unsuitable technique in counting, while many of the higher counts have probably been made on milk derived from udders that were not strictly normal. Von Darányi (1941), who took special care in preventing contamination of the udder and who discarded the fore-milk, found that nearly all healthy cows from the Veterinary High School herd yielded milk having a plate count less than 100 per ml. Strynadka and Thornton (1937), on the other hand, who used the direct microscopic method, found that the bacterial counts on 22 samples of aseptically drawn milk ranged from 10,000 to 370,000 per ml. Considering the extraordinary frequency of mastitis (see Minett 1932, Hucker *et al.* 1932, Diernhofer 1933), 50 per cent. of the animals in a herd often showing disease of one or more quarters, it is very difficult to arrive at any definite conclusion on the probable numbers of bacteria in milk coming from apparently healthy udders. If the udder is diseased, streptococci, *Br. abortus*, tubercle bacilli, and other organisms may be excreted in the milk in large numbers—sometimes running into several thousands per ml.

When aseptic precautions are not employed, the milk is liable to be contaminated with bacteria from the outside of the udder, the interior of milk vessels and utensils, and dust in the atmosphere of the milking shed. Of these various sources, far and away the most important is **unsterilized milking equipment.** The total number of organisms gaining access from the air and from dust is almost negligible compared with that derived from the surfaces of unsterilized pails, coolers, cans, strainers, clarifiers, and bottle fillers. Unless these utensils are actually sterilized—preferably by steam—their surfaces become coated with bacteria of various types, which may contribute enormous numbers of micro-organisms to the milk.

An additional source of contamination is the **human personnel.** If wet milking is practised, considerable numbers of organisms are liable to get washed into the milk from the milker's hands, as well of course as from the exterior of the udder and teats, unless these are thoroughly cleansed. Though numerically few, the organisms reaching the milk in this way may be of considerable public health importance, particularly if the milker happens to be an intestinal carrier of typhoid, paratyphoid, dysentery, or food-poisoning bacilli. The milker constitutes a further source of

danger if he is carrying hæmolytic streptococci or diphtheria bacilli in his throat or nose, since these organisms may gain access to the milk *via* the cough spray.

Apart from initial contamination of the milk, **imperfect cooling** is often responsible for the presence of large numbers of bacteria in any given sample. However carefully milk is produced, sooner or later, provided it is kept at a suitable temperature, it will go sour or putrid as the result of bacterial multiplication. If it is to remain sweet for more than a few hours, all milk should be cooled immediately after production to a temperature of 10° C. or below.

It may be noted that the **keeping quality** of the milk is determined partly by the degree of initial contamination and partly by the temperature at which it is kept. Milk produced under really cleanly conditions has a considerable bacteriostatic power, and shows little bacterial multiplication for several hours, even when incubated at a favourable temperature. On the other hand, the bacteriostatic effect of milk produced under dirty conditions is very slight, and bacterial multiplication sets in rapidly. For this reason it is much easier to distinguish between a milk produced under sanitary, and one produced under insanitary, conditions if the examination is delayed till the milks have stood at a temperature of 60° F. or so for 12–18 hours. After this time a milk produced under clean conditions will still have a low bacterial count, while a milk produced under dirty conditions will contain a large bacterial population.

The **production of clean milk** is largely a matter of technique, not of structural equipment or refinement. Provided all utensils are sterilized by steam, and the surface of the udder and the milker's hands are cleansed, it is possible to produce milk with a very low bacterial content even under unfavourable conditions. It is, however, not easy to maintain a satisfactory technique day in and day out unless suitable conditions and appliances are provided for the workers.

Types of Bacteria in Milk

The bacteria present in milk from healthy cows may be classified into the following groups:

1. Acid-forming Bacteria.—These organisms ferment the lactose in the milk with the production of acids, mainly lactic acid, which combine with the calcium caseinogenate, liberating free caseinogen; this, being insoluble in water, is precipitated in the form of a smooth, gelatinous curd. which shows little tendency to contract and squeeze out fluid. Lactic streptococci constitute some of the most important members of this group. One particular member is often referred to as *Str. lactis*, but as we have seen in Chapter 24 the definition of this species is very difficult Most of these organisms appear to be of vegetable origin, being found on corn, beans, peas, cabbage, etc. (Stark and Sherman 1935). Certain staphylococci, which are not infrequently found in the udder, are also active members of this group. We must further include the lactobacilli, which, however, under ordinary conditions do not appear to proliferate very actively.

2. Gas-forming Bacteria.—These organisms ferment lactose with the production of both acid and gas. They produce a smooth, gelatinous curd, which is often riddled with gas bubbles. The acid produced is largely acetic, which imparts an unpleasant flavour to the milk. Coliform bacilli are among the commonest representatives of this group, which includes, however, certain anaerobic organisms such as *Cl. welchii* and *Cl. butyricum*.

CHAPTER 93

THE BACTERIOLOGY OF MILK

Sources of Bacteria in Milk

EVEN when drawn with aseptic precautions, milk always contains a certain number of bacteria which are derived from the milk ducts of the **cow's udder.** Their numbers vary considerably from quarter to quarter and from cow to cow, and are highest in the fore-milk and lowest in the strippings. The average plate count of aseptically drawn milk has been given by different workers as less than 10 per ml. to several thousand. Many of the lower counts have probably underestimated the true number owing to unsuitable technique in counting, while many of the higher counts have probably been made on milk derived from udders that were not strictly normal. Von Darányi (1941), who took special care in preventing contamination of the udder and who discarded the fore-milk, found that nearly all healthy cows from the Veterinary High School herd yielded milk having a plate count less than 100 per ml. Strynadka and Thornton (1937), on the other hand, who used the direct microscopic method, found that the bacterial counts on 22 samples of aseptically drawn milk ranged from 10,000 to 370,000 per ml. Considering the extraordinary frequency of mastitis (see Minett 1932, Hucker *et al.* 1932, Diernhofer 1933), 50 per cent. of the animals in a herd often showing disease of one or more quarters, it is very difficult to arrive at any definite conclusion on the probable numbers of bacteria in milk coming from apparently healthy udders. If the udder is diseased, streptococci, *Br. abortus*, tubercle bacilli, and other organisms may be excreted in the milk in large numbers—sometimes running into several thousands per ml.

When aseptic precautions are not employed, the milk is liable to be contaminated with bacteria from the outside of the udder, the interior of milk vessels and utensils, and dust in the atmosphere of the milking shed. Of these various sources, far and away the most important is **unsterilized milking equipment.** The total number of organisms gaining access from the air and from dust is almost negligible compared with that derived from the surfaces of unsterilized pails, coolers, cans, strainers, clarifiers, and bottle fillers. Unless these utensils are actually sterilized—preferably by steam—their surfaces become coated with bacteria of various types, which may contribute enormous numbers of micro-organisms to the milk.

An additional source of contamination is the **human personnel.** If wet milking is practised, considerable numbers of organisms are liable to get washed into the milk from the milker's hands, as well of course as from the exterior of the udder and teats, unless these are thoroughly cleansed. Though numerically few, the organisms reaching the milk in this way may be of considerable public health importance, particularly if the milker happens to be an intestinal carrier of typhoid, paratyphoid, dysentery, or food-poisoning bacilli. The milker constitutes a further source of

danger if he is carrying hæmolytic streptococci or diphtheria bacilli in his throat or nose, since these organisms may gain access to the milk *via* the cough spray.

Apart from initial contamination of the milk, **imperfect cooling** is often responsible for the presence of large numbers of bacteria in any given sample. However carefully milk is produced, sooner or later, provided it is kept at a suitable temperature, it will go sour or putrid as the result of bacterial multiplication. If it is to remain sweet for more than a few hours, all milk should be cooled immediately after production to a temperature of 10° C. or below.

It may be noted that the **keeping quality** of the milk is determined partly by the degree of initial contamination and partly by the temperature at which it is kept. Milk produced under really cleanly conditions has a considerable bacteriostatic power, and shows little bacterial multiplication for several hours, even when incubated at a favourable temperature. On the other hand, the bacteriostatic effect of milk produced under dirty conditions is very slight, and bacterial multiplication sets in rapidly. For this reason it is much easier to distinguish between a milk produced under sanitary, and one produced under insanitary, conditions if the examination is delayed till the milks have stood at a temperature of 60° F. or so for 12–18 hours. After this time a milk produced under clean conditions will still have a low bacterial count, while a milk produced under dirty conditions will contain a large bacterial population.

The **production of clean milk** is largely a matter of technique, not of structural equipment or refinement. Provided all utensils are sterilized by steam, and the surface of the udder and the milker's hands are cleansed, it is possible to produce milk with a very low bacterial content even under unfavourable conditions. It is, however, not easy to maintain a satisfactory technique day in and day out unless suitable conditions and appliances are provided for the workers.

Types of Bacteria in Milk

The bacteria present in milk from healthy cows may be classified into the following groups:

1. Acid-forming Bacteria.—These organisms ferment the lactose in the milk with the production of acids, mainly lactic acid, which combine with the calcium caseinogenate, liberating free caseinogen; this, being insoluble in water, is precipitated in the form of a smooth, gelatinous curd. which shows little tendency to contract and squeeze out fluid. Lactic streptococci constitute some of the most important members of this group. One particular member is often referred to as *Str. lactis*, but as we have seen in Chapter 24 the definition of this species is very difficult Most of these organisms appear to be of vegetable origin, being found on corn, beans, peas, cabbage, etc. (Stark and Sherman 1935). Certain staphylococci, which are not infrequently found in the udder, are also active members of this group. We must further include the lactobacilli, which, however, under ordinary conditions do not appear to proliferate very actively.

2. Gas-forming Bacteria.—These organisms ferment lactose with the production of both acid and gas. They produce a smooth, gelatinous curd, which is often riddled with gas bubbles. The acid produced is largely acetic, which imparts an unpleasant flavour to the milk. Coliform bacilli are among the commonest representatives of this group, which includes, however, certain anaerobic organisms such as *Cl. welchii* and *Cl. butyricum.*

3. Proteolytic Bacteria.—These organisms secrete one or other, or both, of two ferments—rennet and casease. Rennet acts in two stages; in the first stage the calcium caseinogenate is converted into a soluble form of casein; in the second stage this is precipitated as calcium caseinate by the calcium salts present in the milk. The resulting clot gradually contracts, and squeezes out a more or less clear fluid, which is known as whey; the whey contains the sugar, salts, and other proteins—lactalbumin and lactoglobulin—in the milk. Casease is a proteolytic enzyme, which digests the proteins present in the milk, breaking them down to proteoses, peptones, and amino-acids.

When the rennet predominates, a firm white curd is produced, which is slowly digested by the casease. When the casease is in excess, either no coagulation at all may occur, or a soft flocculent clot is formed, which is rapidly peptonized.

Many organisms fall under this heading: (*a*) spore-bearing aerobes, such as *B. subtilis* and *B. mesentericus*; (*b*) *Proteus vulgaris*; and (*c*) staphylococci and micrococci. Some of the organisms in this group also ferment lactose, so that the milk is rendered acid, besides being clotted and digested.

4. Alkali-forming Bacteria.—These organisms render the milk alkaline, presumably by acting on the proteins. Some of them also secrete lipase, and the combined effect is to saponify the fat, and convert the milk into a yellow translucent whey-like fluid. This action is not often seen, since the members of this group of bacteria are overgrown by members of other groups, which produce acid, coagulation, or peptonization. Organisms belonging to this group comprise *Bact. alkaligenes*, and some of the aerobic spore-bearers.

5. Inert Bacteria.—Many bacteria produce no visible change in milk and are hence called inert. Some of the udder cocci are included in this group. Members of the *Achromobacterium* group, most of which are probably derived from water, are also relatively inert. It may be noted that most of the pathogenic organisms which may be present in milk belong to this group.

Pathogenic Bacteria in Milk.—Apart from the organisms that we have described as being normally present in milk, there are others which are sometimes found in pathological conditions of the cow's udder, or which gain access to the milk from an infected water supply or from some person handling the milk.

Tubercle bacilli.—The presence of these organisms in milk depends on the frequency of bovine tuberculosis. In Great Britain this disease is very prevalent, about 40 per cent. of cattle reacting to the tuberculin test. Though it is true that tubercle bacilli may be excreted in the milk in the absence of any definite disease of the udder (Report 1909), some degree of tuberculous mastitis can generally be demonstrated—though not always clinically—in cows passing infected milk. It is probable that on an average about 0·5 per cent. of all milch cows in this country are excreting tubercle bacilli in the milk (see Chapter 59). The proportion of market samples of raw milk containing these organisms depends to a considerable extent on the degree to which the milk is bulked, but an average figure of about 7 per cent. may be taken for the country as a whole (Report 1932). The numbers of tubercle bacilli excreted by a single cow are variable from animal to animal, and from day to day, but it is probable that they may reach several hundred or even thousand per ml. (see Pullinger 1934).

Br. abortus.—This organism is responsible for contagious abortion of cattle, which is probably economically more important in this country than tuberculosis.

The udder is frequently infected, even in animals that have not aborted (see Chapter 75), though no lesions can be detected by clinical examination. The bacilli are excreted regularly or intermittently in the milk. Their numbers are usually greatest at the beginning of lactation, when they may reach as many as 200,000 per ml., but in the later stages they diminish and rarely exceed 2,000 per ml. (Stockmayer 1936). The udder may remain infected for years. About 30 per cent. of samples of raw mixed milk offered for human consumption appear to contain this organism.

Streptococci.—Mastitis streptococci are of various types, the most important being *Str. agalactiæ* (see Chapter 24). They are excreted in variable numbers in the milk of cows suffering from mastitis. This disease is extremely common, and affects not only the poorer herds, but even herds producing high-grade milk. Pullinger (1935), for example, found that the milk from 10 out of 12 herds producing Certified milk and 12 out of 14 herds producing Grade A tuberculin-tested milk contained mastitis streptococci when examined at intervals over a period of 15 months. The majority of streptococci causing mastitis are probably non-pathogenic for man, but occasionally a strain of human type invades the udder, and may be responsible for outbreaks of scarlet fever or septic sore throat in persons consuming the milk (see Bendixen and Minett 1938, Dublin *et al.* 1943). The milk may also be contaminated directly with these organisms from persons who are either suffering from streptococcal throat lesions, or who are carrying these organisms in their throat or nasopharynx (see Henningsen and Ernst 1939). Most outbreaks of milk-borne streptococcal infection appear to result from the former method of infection. Though pathogenic streptococci must often gain access to milk from human cases and carriers, their rate of multiplication in raw milk at ordinary temperatures is usually too slow for them to render the milk sufficiently infective to cause disease (see Pullinger and Kemp 1937).

Staph. aureus.—This organism is a not infrequent cause of mastitis. It is often found in the apparently healthy udder, but in cows suffering from mastitis it may be present in large numbers in the milk. Its public health importance lies in the fact that, under favourable conditions, it may multiply in the milk and give rise to a toxin capable of producing gastro-enteritis in human beings (see p. 1605).

C. diphtheriæ.—This organism occasionally finds its way into the milk from the throat or nasopharynx of a human carrier or case of diphtheria. Very occasionally it becomes implanted on ulcers on the cow's teats. Such an occurrence is peculiarly dangerous, since the milk is uniformly infected (for references, see Goldie and Maddock 1943).

Typhoid, paratyphoid, food-poisoning, and dysentery bacilli.—These important pathogenic organisms, which may occasionally contaminate the milk, are usually derived from human or other extraneous sources (see p. 1542).

Quality in Milk. Cleanliness and Safety

Quality is a composite, not a single, attribute of milk. There are, for example, (1) the nutritive quality, (2) the cleanliness, (3) the keeping quality, (4) the pasteurizability, and (5) the safety of milk, to mention only five of its most important attributes. Leaving aside the nutritive quality, which can be determined only by chemical analysis and animal feeding experiments, we may consider for a moment what we mean by the other four properties.

By **cleanliness** is generally understood the freedom of the milk from extraneous matter, from blood, and from an undue number of leucocytes and bacteria. It is an unsatisfactory term, but by general usage it has come to bear this connotation.

The **keeping quality** of the milk refers, of course, to the length of time it will remain sweet, and free from odours and tastes that render it unpalatable.

The **pasteurizability** of the milk is a term devised to indicate the suitability of the milk for heat treatment. It is, of course, a mistaken idea that any milk can be pasteurized. A milk that is too acid will clot when the temperature is raised, and the resultant product will have to be discarded. Again, as Anderson and Meanwell (1933) have shown, some milks contain large numbers of heat-resistant bacteria, which are not destroyed by pasteurization, and which therefore prevent the pasteurized product from conforming to the legal standard.

The **safety** of milk is a term denoting its freedom from bacteria capable of giving rise to disease in man or animals. It is by some writers confused with cleanliness, but there is no necessary or constant relationship between these two properties. Dirty milks, if free from pathogenic bacteria, may be quite safe, while very clean milks are not infrequently dangerous.

It has already been pointed out that pathogenic bacteria in milk may come from (1) the udder, such as the tubercle bacillus, *Br. abortus*, and some streptococci and staphylococci; (2) the infected nasopharynx of human beings handling the milk, such as hæmolytic streptococci and diphtheria bacilli; (3) excretal material gaining access either from the hands of human beings, or indirectly from water contaminated with urine or fæces—usually of human origin; in one or other of these ways typhoid, paratyphoid, dysentery, and food-poisoning bacilli may be carried into the milk. These are the organisms responsible for *dangerous* milk. Those responsible for *dirty* milk, on the other hand, come from various sources, particularly unsterilized milk utensils, caked mud and manure on the cow's udder, dirt on the milker's hands, and from the fore-milk in the teat canal. Provided the cow is healthy, provided that none of the human beings handling the milk is a carrier of pathogenic bacteria, and provided that the water supply is pure, dirt and bacteria may gain access to the milk in considerable quantities without endangering the health of those consuming it. On the other hand, if pathogenic bacteria find their way into the milk from one of the sources quoted above, no matter in how cleanly a manner the milk is produced, it is a potentially dangerous and unsafe milk.

These conclusions are borne out by epidemiological experience, which has shown that several outbreaks of disease have followed the consumption of milk of the highest standard of cleanliness. Without discussing this subject further, we shall probably be wise to regard cleanliness and safety as two entirely separate attributes of milk.

For human consumption it is desirable, of course, that milk should be both clean and safe. Clean milk is more æsthetically desirable, it has a better flavour, and it keeps longer. Moreover, it is not likely to contain any of those toxic substances resulting from undue bacterial proliferation, which have an irritating effect on the gastro-intestinal tract—particularly of infants (see Park and Holt 1903 and Chapter 72). The fewer organisms there are in milk, and the more bacterial proliferation is checked, the less liable is the milk to give rise to digestive disturbance of this type.

As regards safety, it will be clear that *no raw milk can ever be regarded as com-*

pletely safe for human consumption. The frequency of disease in cattle, the risk of contamination from human and other sources, and the suitability of the milk itself as a medium for bacterial multiplication, combine to render the consumption of raw milk potentially dangerous. The only satisfactory way of eliminating this danger is by pasteurization or some other form of heat treatment.

Bacteriological Grading of Milk

From a public health point of view it is usual to grade milk bacteriologically partly according to cleanliness and partly according to safety. We may consider briefly the various methods available for these purposes.

Grading according to Cleanliness.

For a detailed description of the methods used and a study of their experimental errors, and for a critical discussion on the interpretation of their results, the reader is referred to the monograph by Wilson and his colleagues (1935).

Sampling.—Since the answer given by any test is determined so largely (*a*) by multiple factors involved in the production and subsequent handling of the milk; (*b*) by the care with which the milk is sampled, and (*c*) by the time-temperature conditions under which the sample is taken and kept prior to analysis, it follows that it is unwise to pay too much attention to the results of any single examination. The most satisfactory procedure is to make frequent and regular examinations of the milk of any given producer throughout the year, and insist that a given proportion, for example 75 per cent., of the samples should come up to a given standard. In this way some allowance will be made for factors over which the producer is unable to exercise complete control, while at the same time ensuring that the conditions of production as a whole are kept at a reasonably high level.

Every endeavour should be made in the sampling of the milk to obtain a homogeneous distribution of organisms and fat. With regard to the subsequent treatment of the sample, two alternative procedures are available. If the intention is to test the cleanliness of production, it is desirable to expose the sample after collection to an agreed temperature for a given length of time, in order that the latent contamination in milk produced under bad conditions may have time to develop. When testing milk delivered to the consumer, on the other hand, it is desirable to ice the sample at once, so as to obtain information on the degree of bacterial contamination at the time of delivery by the distributor.

The sample may be examined by the following tests:

(1) **The Sediment Test.**—The amount of extraneous matter in the milk is determined either by filtration through a cotton pad, or by centrifugation. A simple sediment test of this sort is of value in controlling the gross dirt in milk and in education of the unhygienic farmer. Since, however, filtration through muslin gauze on the farm will remove dirt of this type, the absence of an obvious sediment must not be taken to mean that the conditions of production were satisfactory. Most of the bacteria in milk come, not from gross dirt, but from unsterilized utensils. Indeed, actual manure can be added to the milk without producing any marked increase in the bacterial content; for this reason a sediment test is useful for the detection of gross particulate matter, the presence of which is not likely to be detected by purely bacteriological tests.

(2) **The Cellular Content.**—Normal milk contains various types of cells, the number of which is estimated by different workers at between about 200,000 and 1,000,000 per ml. These estimates probably err on the high side, though it may be noted that Strynadka and Thornton (1937) on a series of seven milks obtained cell counts ranging from 80,000 to 5,100,000 per ml. According to Prouty (1934), milk from perfectly normal udders contains, as a rule, less than 100,000 cells per ml. But the perfectly normal udder is almost a curiosity, and for practical purposes, therefore, we must allow a considerable margin on this figure. An abnormally high cell count may be due to retention of the milk in the udder, which leads to desquamation of the epithelial cells in the alveoli and ducts, to acute or chronic inflammation, which brings about a rise in the polymorphonuclear leucocytes, or to some other cause. A mere count of the cells present affords little information about the quality of the milk, and it would be unwise to condemn a milk solely on account of an increased cell content. If long-chained streptococci are found in addition, the probability is that the cow is suffering from mastitis. Much more information can be obtained by a differential count, but the real value of this method lies in the help it gives to the veterinarian who is engaged in a study of the individual cow.

(3) **The Breed Smear Method.**—The general technique of this method is to spread 0·01 ml. of the milk over 1 sq. cm. on a glass slide, to fix and de-fat, to stain with methylene blue, to count the number of individual organisms—the Breed "individual" count—or preferably the number of groups of organisms, individual organisms each being regarded as a group—the Breed "clump" count—in a given number of fields, and finally to calculate the number of organisms in 1 ml. of the original milk. The result obtained affords an index of the total *stainable* organisms present, not necessarily of the total organisms. The chief value of this method lies in its rapidity, which enables an opinion to be formed on the bacterial cleanliness of a milk within a few minutes. It is particularly suitable for use in collecting stations to which milk from individual farms is brought before being mixed and sent up to towns in large rail or road tanks. Unsatisfactory milks, which would taint the rest, can be picked out quickly, and returned to the producer. With a little experience, a mere glance over a few fields is sufficient to indicate the general quality of the milk. The Breed Smear method is also of value to the farm inspector in indicating the probable nature of the defect in unsatisfactory milk. Thus the presence of large masses and clumps of bacteria suggests unsterilized milk utensils; the presence of numerous organisms arranged in pairs or small units suggests inadequate cooling; the presence of long-chained streptococci associated with a high leucocyte count indicates mastitis, and so on (see Breed 1929).

(4) **The Keeping Quality Test.**—The milk is kept in a special bottle at a given temperature, such as 60° F. or 70° F., and examined every 8 or 12 hours until it becomes sour or putrid. As a general method for controlling the hygienic quality of the milk, this test performs a useful function, but the fact that the end-point is entirely subjective necessarily exposes the result to a very large experimental error. Some degree of objectivity can be introduced into the test by the use of alcohol. If 1 ml. of a 68 per cent. solution of ethyl alcohol is added to 1 ml. of the milk and the tube is inverted, precipitation of the casein occurs in milks that are near the souring point. On the whole, there is good agreement between the taste and the alcohol tests, the latter being slightly more sensitive (see Anderson and Wilson 1945). An indirect method, which appears to afford a good indication

of the keeping quality, is a modified methylene blue test carried out at 60° F. (see Provan, Dudley and Thomas 1936).

(5) **The Plate Count.**—This is one of the most widely used methods for the bacteriological grading of milk according to cleanliness. It is, however, exposed to criticism on so many grounds that it is doubtful whether its continued use is justifiable. Ostensibly the plate count measures the numbers of bacteria in the milk, but in fact it does not. The bacteria in raw milk are of many different kinds and come from varied sources. Often a large proportion are dead, while those that are alive differ in their nutritional, respiratory, and temperature requirements, so that no one medium incubated for a given length of time at a given temperature under aerobic conditions can possibly afford a true estimate even of the living organisms present. More important still, however, is the fact that many of the bacteria are distributed, not individually, but in chains and groups of varying sizes. The colonies developing on plates are derived therefore, not solely from individual organisms, but also from aggregates containing varying numbers of bacteria. In consequence the plate count merely registers the number of bacterial particles capable of forming colonies under the particular conditions selected. Since the average number of bacteria per clump is variable from one milk to another, and not constant from time to time even in milk of the same origin, it follows that the figures yielded by the plate count are arbitrary, are not strictly comparable, and have no absolute significance.

When it is further pointed out that these clumps of bacteria may disintegrate to a variable and quite uncontrollable extent during the process of dilution, leading in extreme instances to errors of 1,000 per cent. (Ward 1926), and that many of the individual steps in the technique of the count are very difficult to standardize, and even when standardized as nearly as possible are attended by a large experimental error, it will be realized that the figures yielded by the plate count are not merely arbitrary, but are also only approximate. (For a description and numerical assessment of the various errors of dilution, incubation, counting, personal bias and personal variability, sampling, overcrowding, and so on, see Wilson *et al.* 1935.)

Even were it possible to standardize the technique of the plate count, it would still be necessary to allow a margin of $\pm$ 50–90 per cent. on the result of any one milk, depending on the number of plates used for each dilution. Even this estimate would often fall short of the real variation met with in practice (Mattick *et al.* 1935). However accurate the plate count may be for the enumeration of bacteria in pure broth cultures, it is plainly unsuitable for this purpose when applied to milk. Because the results are expressed quantitatively in figures extending over a wide range, they afford a fictitious appearance of accuracy which leads, not only in laymen, but even in public health officials, to a wholly unjustifiable feeling of confidence in their value. It is not denied that the plate count can be used as a rough yard-stick for the grading of milk, but it is denied that it can be used as a millimetre rule. As scientific bacteriologists we can hardly condone a practice which is little short of bacteriological prostitution.

(6) **The Coliform Test.**—Like the plate count, this method has been extensively used in the past for the grading of milk without any real appreciation of the fundamental assumptions on which it rests. We have seen that in the analysis of *water* the coliform test affords us the most delicate index we have of excretal pollution. The main reasons for this are that (1) in this country something like 90 per cent. of waters giving a positive presumptive coliform reaction in MacConkey broth are

proved on further examination to contain typical *Bact. coli* of excretal origin (Bardsley 1934); (2) organisms of the *Bact. coli* type in water in this country are very frequently derived from human excretal material, and since human fæces and urine may contain pathogenic bacteria, the presence of any excretal pollution, as indicated by the coliform test, must be regarded as potentially dangerous; and (3) as a rule, coliform organisms do not seem to multiply in water under natural conditions; on the contrary, they tend to die out rather rapidly (Houston 1913). In this country, therefore, the coliform count in water indicates the minimal amount of excretal pollution that has occurred.

When we turn to *milk* we find that (1) a considerable proportion—something like 50–70 per cent.—of raw milks in this country in which coliform bacilli are found contain not the true *Bact. coli* but organisms of the intermediate or aerogenes-cloacæ types. These organisms come mainly, not from fæces and urine, but from soil and grain, and their presence therefore in milk cannot be regarded as an index of excretal pollution; (2) the true *Bact. coli* organisms that are found in milk appear to come either directly from cow-dung and manure, or indirectly from unsterilized milk utensils in which bacterial multiplication has occurred. If they are derived from the latter source, they clearly afford no index of *direct* excretal pollution. If they are derived from the first source, their presence may be considered objectionable on the ground that organisms pathogenic for man are sometimes present in the intestinal canal of the cow. The presence, however, in milk of excretal material of bovine origin must be regarded as very much less dangerous for man than that of human origin. (3) Unlike water, milk affords an admirable medium for the growth of coliform bacilli. If it is kept at a temperature of 50° F. or over, a great increase in their numbers may take place, a rise of several thousand-fold often occurring at 60° F. within 24 hours (see Ayers and Clemmer 1918, Finkelstein 1919, Sherman and Wing 1933). Unless, therefore, the milk has been kept at 40° F. or less, an estimation of the coliform bacilli affords only a very imperfect, and often entirely misleading, index of the extent of the original contamination. With a milk produced and kept under ordinary conditions, it is impossible to tell how many of the coliform bacilli gained access at the time of production, and how many are due to the multiplication of those originally present.

It will thus be seen that none of the three premises on which the scientific application of the coliform test to water in this country is based holds true for milk. Even a differentiation of the coliform group into its constituent types is not likely to help us, since (*a*) it is impossible to tell how many of the different types were original contaminants and how many have resulted from growth, and (*b*) organisms of the fæcal coli group are not necessarily derived directly from excretal material, but may come from unsterilized milk utensils on which they have been multiplying perhaps for several generations.

The presence of coliform bacilli in small numbers in water or milk is not in itself objectionable; it is merely as an index of the possible accompanying presence of pathogenic organisms that it is of importance. In milk, the coliform test cannot be used as an index of direct excretal pollution, for though it is true that if manure gains access to milk, coliform organisms will probably be found, the reverse conclusion does not hold true. There are so many other sources on the farm for these organisms that their presence in milk cannot be held to justify the conclusion that the milk has necessarily been contaminated with excretal material. The coliform test on milk fails to provide us with that specific qualitative information which it

supplies in the case of water, and as a general method of grading, therefore, it seems to be unsuitable. It may serve a useful purpose in the examination of the highest quality raw milk, since such milk often fails to show the presence of coliform bacilli in 1 ml. quantities even several hours after production (Mattick and Williams 1925). Its use, however, in this connection is purely empirical, merely serving as an index of contamination of the milk from environmental sources. Again the test may be of some empirical value in the control of pasteurization, since the practical absence of coliform bacilli from pasteurized milk examined immediately after processing affords, except with very clean milks, a fairly good indication that pasteurization has been carried out efficiently.

(7) **The Modified Methylene Blue Reduction Test.**—The general technique of this test is to add 1 ml. of a standard methylene blue solution to 10 ml. of milk in a test tube, to insert a sterile rubber cork, to invert the tube once or twice so as to mix the dye with the milk, to incubate in a constant-temperature water-bath at 37°–38° C. in complete darkness, to invert the tube every half-hour, and to observe the time at which the dye is decolorized. If reduction has not occurred within a given time, then no further observations need be made (see Wilson *et al.* 1935).

Reduction depends partly on the absorption of oxygen and the production of reducing substances by the organisms, and partly on the presence of a natural reducing system in the milk itself (see Hobbs 1939). Since some of the reducing enzymes and some of the organisms are adsorbed on to the fat, and since the fat globules themselves play an important mechanical part in increasing the surface available for enzyme action and in affecting the visual depth of colour, the necessity of preventing an accumulation of cream at the surface will be realized; hence the necessity of half-hourly inversion.

The rate at which methylene blue is reduced in milk depends partly on the number of organisms and partly on their metabolic activity. For this reason it affords a very good index, not only of the bacterial cleanliness of the milk, but also of its keeping quality. The test is unsuited for the milk of individual cows, and for freshly pasteurized milk, but affords quite a good index to the keeping quality of pasteurized milk as delivered to the consumer (Ciani 1939). Its chief value lies in affording a fairly rapid means of assessing the general hygienic quality of raw mixed milk. Its technical simplicity, its cheapness, and its extremely small experimental error render it admirably suited for the routine control of this type of milk. The reduction time to be laid down must depend on the level of cleanliness desired. A milk of high quality, which has been kept for about 12 hours at atmospheric temperature in this country, should not reduce methylene blue in less than about 8 hours in the winter or 7 hours in the summer, while one of fairly good quality should not reduce the dye in less than about 6 and 5 hours respectively.

Besides the advantages already noted, the reduction test has certain other advantages over the plate count. The first is that the result does not appear to be affected to any considerable extent by the degree of aggregation of the bacteria, which is one of the most disturbing features of the plate count on milk. The second is that the test affords a much more delicate index of bacterial growth than the plate count. It will be remembered (Chapter 4) that during the lag phase bacteria increase in size for some time before they commence to divide. The plate count therefore remains approximately constant during this phase. The reduction time, on the other hand, falls rapidly, owing to the active metabolism of the organ-

isms. It serves, in fact, as a remarkably sensitive index of growth, and is hence peculiarly fitted to gauge the keeping quality of the milk. The plate count yields a *static* picture of the bacterial population: the methylene blue reduction test affords a *dynamic* picture. (For comparison between the two tests see Wilson *et al.* 1935, Nichols and Edwards 1936, Asdrubali 1939, Barkworth, Irwin and Mattick 1941).

(8) **The Resazurin Test.**—The principle of this test, which owes its practical introduction mainly to the work of Ramsdell, Johnson and Evans (1935), is the same as that of the methylene blue test. The test consists essentially in adding to the milk a solution of resazurin to give a final concentration of 1/200,000, incubating at a given temperature, and observing the time taken to bring about a change in the colour of the dye, or alternatively noting the colour reached after a given time. The colour passes from blue, through various shades of purple and mauve, to pink, and ultimately to complete decolorization. The change from blue to pink is due to the irreversible reduction of resazurin to resorufin: the change from pink to colourless is due to the reversible reduction of resorufin to hydroresorufin. The colour can be assessed by a suitable comparator. Numerous methods of performing this test have been described (see Johns and Howson 1940, Davis, Newland and Knuckey 1943). In this country a 10-minute test is used for the control of "platform" milk, that is producers' milk arriving at a creamery, in order to see whether it is clean enough to be bulked with other milk. A longer test is employed by agricultural bacteriologists for the control of the general quality of milk at the time of production.

The advantages of the resazurin over the methylene blue test are mainly two. Firstly, resazurin changes in colour rather more rapidly, and though complete reduction takes as long as or even longer than methylene blue, useful information can be obtained by noting a change in colour from blue to lilac or pink. Secondly, resazurin is more sensitive to the cell content of milk, and is therefore regarded by some workers as of value in the detection of mastitis. The practical importance of these two advantages is dubious. Admittedly a 10-minute test is useful as a screen for grossly contaminated milk; but if the resazurin test is to be used as an index of keeping quality and the reduction of the dye observed to the pink stage, then there is practically no saving of time over the methylene blue test (Anderson and Wilson 1945). Watts and Stirling (1944), in a very careful investigation, found that the resazurin test, even when carried out on individual quarter samples, was of limited value for the routine diagnosis of mastitis, and practically valueless for the detection of milk from infected cows when mixed with normal milk; in fact, as much as 73 per cent. of the herd milk could be derived from cows suffering from mastitis without significantly altering the result of the resazurin test.

The disadvantages of the resazurin test are that the dye is not easy to standardize and is very sensitive to sunlight, that the colour change has to be followed by a comparator, and that the lilac and pink stages are not easily appreciated by persons whose vision is insensitive to red colours. In general terms it may be said that the resazurin test is more influenced by abnormal milk such as colostrum, late-lactation milk, milk from cows with mastitis, and by milk containing organisms with low reducing powers, but that the methylene blue test affords the better indication of bacterial contamination of the milk.

(9) **The Laboratory Pasteurization Test.**—This consists in making a plate count

before and after pasteurization in the laboratory, and noting the numerical reduction that has occurred (Anderson and Meanwell 1933). Its main purpose is to detect the presence of heat-resistant and thermophilic bacteria in the milk, which may be present in such numbers as to prevent the pasteurized product from conforming to the official standards laid down. It is essentially a test for use in processing depots.

It will be realized that numerous tests are available for assessing the general cleanliness of milk, and that each of these tests affords an answer to a different question. Complete correspondence of the results of the different tests cannot therefore be expected. Experience has shown, however, that the Breed clump count, the plate count, and the modified methylene blue reduction test are all fairly highly correlated with each other. On individual milks, of course, the reduction test and the plate count may give widely different results, owing mainly to the extraordinary high experimental error of the plate count, but on an average the results of these tests are very similar. For practical purposes, therefore, there seems to be no advantage in using the complex, expensive, and highly inaccurate plate count in preference to the simple, inexpensive, and accurate reduction test. From a public health point of view, probably only two divisions need be made on the basis of *cleanliness*, namely (*a*) into milk that is suitable and (*b*) into milk that is not suitable for human consumption in the liquid state. We would again emphasize that a *clean* milk is not necessarily a *safe* milk.

Grading according to Safety.

The pathogenic organisms for which search is commonly made in milk are the tubercle bacillus, *Br. abortus*, and hæmolytic streptococci. The methods employed in searching for the first two organisms have already been described in Chapters 59 and 75 respectively.

The presence of mastitis streptococci in milk may be demonstrated microscopically or by culture, but according to Minett (1935) the microscopic method detects only about half of the cases that are positive culturally. The cultural method is, therefore, the method of choice. Individual quarter samples of the fore-milk should be plated out on to a suitable blood agar medium and a study made of the colonies that develop (see p. 565). The differentiation of *Str. agalactiæ* from other closely related types has been discussed in Chapter 24.

Milk Designations.—The grades of milk in England and Wales are defined in the Milk (Special Designations) Orders and Regulations 1936 to 1944. Briefly, four main grades of milk are laid down—Tuberculin Tested, Accredited, Pasteurized, and Heat-Treated. Some of the more important requirements affecting the production and testing of these milks are set out in Table 205.

It will be noted that (1) Tuberculin Tested milk may be pasteurized: (2) Accredited milk does not have to come from herds subjected to a tuberculin test, and hence cannot be guaranteed to be free from tubercle bacilli; (3) Milk may be pasteurized either by the Holder method at 145°–150° F. for 30 minutes or by the High Temperature Short Time method at 162° F. for 15 seconds; (4) No regulations are laid down for the production of Heat-Treated milk; (5) Tuberculin Tested (Pasteurized) and ordinary Pasteurized milk have to conform to the standard of Heat-Treated milk as well as to a plate count test; (6) There is no official designation for ordinary raw milk, and no bacteriological standard of cleanliness

TABLE 205

GRADES OF MILK LAID DOWN IN THE MILK (SPECIAL DESIGNATIONS) ORDERS AND REGULATIONS 1936–1944 FOR ENGLAND AND WALES.

Designation.	General Conditions.	Bacteriological Requirements.	Remarks.
Tuberculin tested.	Tuberculin test on herd at least every 6 months. Veterinary inspection every 6 months.	Must not decolorize methylene blue in 4½ hrs. 1st May to 31st Oct., or in 5½ hrs. 1st Nov. to 30th April.[1] Coliform bacilli absent from 1/100 ml.	(i) If bottled on farm, may be labelled Tuberculin Tested (Certified). (ii) If pasteurized, must not decolorize methylene blue in 30 mins.,[2] must not give a phosphatase reading of over 2·3 Lovibond units, and must have a plate count not exceeding 30,000 per ml.
Accredited.	Veterinary inspection every 3 months.	Same as for Tuberculin Tested milk.	If bottled on farm, may be labelled Accredited (Farm Bottled).
Pasteurized.	Milk must be kept at a temperature (i) of 145°–150° F. for not less than 30 mins. and be immediately cooled to 55° F. or below, or (ii) of not less than 162° F. for at least 15 seconds and be cooled as above.	Must not decolorize methylene blue in 30 minutes,[2] must not give a phosphatase reading of over 2·3 Lovibond units, and must have a plate count not exceeding 100,000 per ml.	Pasteurizing plant must be approved by the licensing authority, and must be equipped with indicating and recording thermometers. Temperature records must be preserved for at least a month. High Temperature Short Time plant must be provided with an automatic flow-diversion valve. The milk shall not be heated more than once.
Heat-treated.		Must not decolorize methylene blue in 30 minutes,[2] and must not give a phosphatase reading of over 2·3 Lovibond units.	No method of processing the milk is laid down. Any milk, therefore, including sterilized milk, that conforms to the bacteriological requirements may be described as Heat-Treated milk.

[1] If the sample is taken before the milk has been placed in bottles or other containers for delivery to the consumer (*i.e.*, producers' milk), it must be kept at atmospheric temperature till 6 p.m. if it is a morning milk, and until 10 a.m. on the following day if it is an evening milk, before it is tested bacteriologically. It is not necessary for every sample to be submitted to both reduction and coliform tests as a routine; it will generally be found convenient in testing producers' milk to have most of the samples examined by the methylene blue test alone, reserving the coliform test for occasional use (see Memo. 1937).

[2] The sample should be taken on the day of delivery, and must be kept at atmospheric shade temperature in transit to the laboratory. In the laboratory itself it must be kept at atmospheric shade temperature not exceeding 65° F. until between 9 a.m. and 10 a.m. on the following day, when the methylene blue test is begun. At no time after sampling should the milk be exposed to the direct rays of the sun (see Report 1944).

or safety is laid down for this type of milk. From the point of view of public health Tuberculin Tested (Pasteurized), Pasteurized and Heat-Treated are the only milks that can be relied upon as being free from the risk of causing disease. All other milks should be heated to the boiling-point before being consumed in the liquid state, if it is desired to ensure the destruction of pathogenic organisms.

Diseases borne by Milk.—From the description that has already been given of the pathogenic organisms that may be found in milk, it will be realized that milk serves as an important vehicle in the spread of disease to man. The frequency of tuberculosis of bovine origin and of undulant fever due to milk-borne organisms has been considered in Chapter 59 and 75 respectively. In these diseases infection of the milk occurs in the udder of the cow itself. In scarlet fever, septic sore throat, and diphtheria, infection occurs from the udder of the cow or from the nasopharynx of some person handling the milk, while in typhoid fever, paratyphoid fever, dysentery, and food poisoning the causative organisms generally gain access to the milk from the infected hands of some human attendant, or probably less frequently from a contaminated water supply.

The true frequency of milk-borne disease is extremely difficult to estimate, partly because the disease is often insidious in its onset and suspicion of the milk supply is not aroused, and partly because isolated cases of milk-borne infections, even if they are recognized as such, are not usually recorded (see Bendixen *et al.* 1937). In this country Savage (1912) attempted to collect the data referring to milk-borne epidemics prior to 1912. Those from 1912 to 1937 have been collected by Wilson (1942) and are summarized in Table 206.

TABLE 206

RECORDED OUTBREAKS OF MILK-BORNE DISEASE IN GREAT BRITAIN IN 1912–1937 (EXCLUDING TUBERCULOSIS AND UNDULANT FEVER, AND OUTBREAKS DUE TO MILK PRODUCTS SUCH AS ICE-CREAM, CHEESE, AND CREAM BUNS). (Wilson 1942.)

Disease.	No. of Outbreaks.	No. of Outbreaks in which Number of Persons affected is stated.	No. of Persons affected in these Outbreaks.
Scarlet fever and septic sore throat	40	34	5,331
Diphtheria	20	18	773
Typhoid fever, paratyphoid fever, and dysentery	39	36	3,229
Gastro-enteritis	14	12	4,346
Total	113	100	13,679

These outbreaks merely represent those of which records are readily available, and almost certainly underestimate the real number. They pay no attention, of course, to sporadic cases of milk-borne infection, nor do they include the 6,000 cases of tuberculosis of bovine origin nor the 400–500 cases of undulant fever, in a large proportion of which infection is milk-borne, that occur annually in Great Britain.

In the United States Armstrong and Parran (1927) record data referring to 612 milk-borne epidemics occurring during the preceding 20 years (Table 207).

TABLE 207

OUTBREAKS OF MILK-BORNE DISEASE IN THE UNITED STATES, 1906–26. (Armstrong and Parran 1927.)

Disease.	No. of Outbreaks.	No. of Cases (incomplete).	No. of Deaths (incomplete).
Typhoid fever	479	14,968	219
Paratyphoid fever	7	434	15
Diarrhœa and dysentery	6	92	5
Septic sore throat	42	21,045	139
Scarlet fever	40	3,939	20
Diphtheria	26	971	7
Miscellaneous diseases	12	878	5
Total	612	42,327	410

This table again affords merely a conservative estimate of the frequency of milk-borne epidemics, and there is reason to believe that many outbreaks are not recognized or are not recorded (Brooks 1933). It will be noted that the relative incidence of enteric fever is very much higher than in Great Britain. During the years 1938 and 1939 the number of outbreaks in the United States transmitted by milk and milk products was 42 and 41 respectively, affecting 1,685 and 2,509 persons (Frank 1940, Fuchs 1941).

Dolman (1941) in Canada collected records of 67 milk-borne outbreaks during the years 1912 to 1939 affecting 8,348 persons; 51 of the outbreaks were of enteric fever and resulted in no fewer than 729 deaths.

We have no space to discuss the epidemiology of milk-borne disease. Apart from the explosive nature of the outbreak, it is interesting to note that in milk-borne scarlet fever and diphtheria the average age incidence is often very much higher than in non-milk-borne epidemics. The majority of the cases may occur in persons of 15 years and over (see Godfrey 1929, Clarke 1936, Hill and Mitra 1936).

Methods for increasing the Safety of the Milk Supply.

These fall into three main categories.

A. Control of Animal Disease.—Reference has already been made in Chapters 59 and 75 to the methods available for diminishing the frequency of tuberculosis and contagious abortion in cattle, and in Chapter 67 to the elimination of mastitis. The success attendant on these measures will depend very largely on the vigour with which they are prosecuted. The eradication of disease, however, from the animal population is essentially an agricultural and veterinary problem to be undertaken in the economic interests of the farmer, and the task, particularly in this country where cattle disease is so widespread, is bound to be a long one. However much, therefore, we may support our veterinary colleagues in their enterprise, we must remember that this mode of approach can afford only a tardy and a partial solution to the problems faced by the public health administrator, namely, that of supplying a safe milk to the human population.

B. Control of the Human Personnel handling the Milk.—However healthy the animals producing the milk may be, there is always danger of its becoming infected directly or indirectly from the nasopharynx or fæces of human carriers of *Str. pyogenes*, *C. diphtheriæ*, *Salm. typhi*, *Salm. paratyphi A* and *B*, dysentery bacilli,

and bacilli of the food-poisoning group. In the United States some attempt has been made to control the human personnel handling the milk. The most frequent examinations made comprise a physical inspection, a careful inquiry into the history of infectious disease, a series of fæcal and urinary examinations for organisms of the enteric and dysentery groups, and nose and throat swabs for streptococci and diphtheria bacilli (see Borman *et al.* 1935). There is no question that close supervision of milk operatives, particularly of those working in pasteurizing depots, is highly desirable. The procedure is, however, costly and is not free from administrative difficulties. Moreover, since the carrier state is often transient or intermittent, it is impossible without almost daily supervision to detect all dangerous persons.

C. Heat Treatment of the Milk : Pasteurization, Boiling, and Sterilization.—The dangers of infection of milk from cattle, from the human personnel, and from water are so great that we shall not be overstating the case if we assert that no raw milk can be regarded as perfectly safe for human consumption. Clearly we must interpret this axiom with discretion, remembering always that the stringency of our precautions must be commensurate with the size of the population at risk. It is very difficult to assess in any particular instance the real danger run by persons consuming a given milk supply, and our safest course is therefore to insist as far as possible that all pathogenic organisms shall be destroyed by some form of heat treatment.

Pasteurization affords the most satisfactory means for this purpose. In this country two methods are permitted. The Holder process consists in raising the milk to a temperature of 145–150° F., holding it at this temperature for 30 minutes, and immediately cooling it to 55° F. or below. If this process is carried out in properly designed plant free from mechanical defects (see Scott and Wright 1935, Dalrymple-Champneys 1935), and supervised by intelligent and conscientious operatives, it can be relied upon to destroy all pathogenic organisms in the milk. In the so-called High Temperature Short Time process the milk must be kept at a temperature of not less than 162° F. for at least 15 seconds and then cooled to 55° F. or below.

The adequacy of heat treatment may be controlled by the *phosphatase test* (Kay and Graham 1935, Kay, Aschaffenburg and Neave 1939, Memo. 1943, Report 1944), which depends on the fact that the enzyme phosphatase, which is normally present in milk, is destroyed by a temperature of 145° F. within 30 minutes or of 162° F. within 15 seconds. The test is carried out by incubating the milk in the presence of a buffered solution of disodium phenyl phosphate. The amount of phenol that is liberated is measured by adding Folin and Ciocalteu's reagent and estimating the depth of the resulting blue colour by a Lovibond tintometer or, more simply and approximately, by a Lovibond comparator. Raw milk gives figures of about 50 blue units, but in properly pasteurized milk the number of units is reduced to 2·3 or less. This is a most valuable test and can be used in practice to ensure that the processing of the milk is carried out satisfactorily. Phosphatase is slightly more resistant to heat than the tubercle bacillus, so that a negative phosphatase result is strong presumptive evidence in favour of the safety of the milk.

The objections that have been raised to pasteurization, though often made on apparently scientific grounds, are determined almost entirely by economic or political motives. The farmer, especially the producer-retailer, may not obtain

such a high return for his milk if he has to pasteurize it himself or send it to a pasteurizing depot as if he sells it directly to the customer in its original raw and possibly dangerous state. Producer-retailers, moreover, are afraid that pasteurization will lead to their being gradually absorbed by the big milk combines, which can of course afford to pasteurize and bottle their milk under very much more favourable conditions than is possible for a small producer. Though appreciating the force of these motives, we must not allow the public health of the nation to be sacrificed to the financial interests of a small section of the community.

One of the chief objections that has been raised is that pasteurization lowers the nutritive value of the milk. The evidence for and against this contention has been reviewed by several workers (see Stirling and Blackwood 1933, Report 1934, 1936, 1937–39, Bendixen *et al.* 1937, Wilson 1942). The main effects of pasteurization by the Holder method at 145°–150° F. for half an hour followed by immediate cooling to 55° F. or below are as follows: (1) the cream line is reduced by about 10–30 per cent. (2) About 5 per cent. of the lactalbumin is coagulated. (3) There is a diminution of about 5 per cent. in the soluble calcium and phosphorus. (4) There is some destruction, amounting usually to about 10 per cent., and at the most to 25 per cent., of Vitamin B_1. (5) There is a variable diminution in the Vitamin C content, dependent on the degree of previous exposure of the milk to light, the presence of copper in the pasteurizing plant, and the amount of dissolved oxygen; at present, the average reduction is about 20 per cent. (6) Some of the iodine —almost certainly less than 20 per cent.—may be driven off as the result of volatilization. (7) A high proportion of the bacteria in the milk are destroyed, leading, as a rule, to a considerable increase in the keeping quality. Against these positive changes may be set a number of negative findings. Thus it is found from feeding experiments on rats and calves that the biological value and digestibility of the proteins is not decreased, that there is no detectable change in the availability of calcium or phosphorus, that there is no loss of Vitamin A or D, and that the total energy of the milk remains unaltered. So far as human beings are concerned, it may be pointed out that milk is a poor source of Vitamins C and D, and that infants fed on milk, whether raw or pasteurized, should therefore always be given a supplement of fruit or vegetable juice and cod-liver oil. The differences between raw and pasteurized milk are far less than those between cows' milk and human milk, or even between summer and winter samples of raw milk (see Kay 1939). Extensive feeding experiments on rats, mice and calves, and comparative investigations on children have failed to show that pasteurization has any significant effect in lowering the total nutritive value of the milk for the growing animal, and no fear need therefore be entertained that a policy of pasteurization will prejudice the nutritional development of the child population.

From a public health point of view there are manifestly strong reasons why all milk intended for consumption in the liquid state by a community of any size should be submitted to pasteurization, the process being, of course, adequately controlled by the appropriate supervising authorities. There is reason to believe that if pasteurization was rendered compulsory and universal, milk-borne disease would practically cease to exist (see Wilson 1942).

If pasteurization is impracticable, then the milk should be *boiled* in the individual household. The most satisfactory way of doing this is to bring it to the boil in a closed vessel, preferably a double saucepan, and cool it immediately to as low a temperature as possible.

Sterilization is the term used for a process which is applied commercially, and which is intended to destroy all but the most resistant spore-bearing organisms. In some plants the temperature is not raised above boiling-point, but more usually the milk is heated under a slight pressure. It is distributed in hermetically sealed bottles. Bacteriologically the milk is perfectly safe, but the partial caramelization which it undergoes renders its flavour unpalatable to most persons.

INDEX

All organisms are listed under the generic names given in the Classificatory Chart on p. 319. Since many rod-shaped organisms have in the past been known under the generic name of *Bacillus*, irrespective of whether or not they belonged to this genus, we have for the convenience of the reader included most of them under the heading Bacillus (non-italicized). This heading should therefore be consulted by those who are doubtful to what genus a given organism belongs.

laboratory infections in, 1721
lemming fever, 1721
Tumours, filtrable, 1976–1981
Twort-d'Herelle phenomenon. *See* Bacteriophage
"Two-stage" hypothesis of antigen-antibody reactions, 208
Tyndallization, 7, 114
Typhoid fever. *See* Enteric fever
Typhoid-paratyphoid group. *See Salmonella*
Typhus fevers, **1841–1862.** *See also Rickettsia*
Brazilian spotted fever, 1847
Brill's disease, 1841, 1842
classical type of, 934, 1842, 1845, 1854
classification of, 1852, 1854
diagnosis of, 1853–1858
by complement-fixation test, 1856
Typhus fevers, diagnosis of, by infection test, 1857
by virus neutralization test, 1857
by Weil-Felix test, 1853–1858
exanthematic fever of Marseille, 1848
experimental in guinea-pig, avitaminosis in relation to, 1197
fièvre boutonneuse, 1848
flea-borne, 1845
gaol fever, 1842
Kenya fever, 1848
louse-borne, 1842
Mexican typhus, 1845
mite typhus 936, 1849
murine type of, 935, 1845, 1854
of Lukes in dogs, 1837
pathology of, 1844
prophylaxis and treatment of, 1858
by serum in, 1861
by vaccination, 1859
Q fever, 1850
Rocky mountain spotted fever, 935, 1846
São Paulo typhus, 1847
scrub typhus, 936, 1849, 1856
shop typhus, 1845, 1856
South African tick fever, 1848
tabardillo, 1845
tick-borne, 1846–1848
trench fever, 1851
tropical typhus of Malaya, 1845, 1849, 1855
tsutsugamushi fever, 936, 1848
Weil-Felix reaction in, 1853–1858
Tyrocidin, 174
Tyrothricin, 174

Ulcerative lymphangitis of horses, 1403
Ulcus molle, 1790
Ultrafiltration, 951
Ultramicroscopic viruses. *See* Viruses animal
Ultra-violet light, disinfecting action of, 105
effect of on bodily resistance, 1203
on proteins, 105
on toxins, 105
use of in photomicrography, 18, 952
Undulant fever, **1692–1706**
diagnosis of, 1702
due to *Br. abortus*, 1697
abortion in, 1698
butter and cheese infections in, 1701
contact infections in, 1701
institutional outbreaks of, 1701
laboratory infections in, 1701, 1702
latent infections in, 1699
milk infections in, 1700
tonsillar infections in, 1703
due to *Br. melitensis*, 1693
epidemiology of, in Malta, 1694
in other countries, 1697
eradication of by stopping of goats' milk, 1695
infection of fæces and urine in, 1694, 1703
due to *Br. suis*, 1702
milk in relation to, 1695, 1699, 1700, 1706
prophylaxis and treatment of, 1706

Unimolecular reaction, similarity of disinfection to, 137–140
Unit of antitoxin, 238
Unitarian conception of antibodies, 248, 285
Uracil, 71
Urethra, normal flora of, 1997
Uric acid, fermentation of in differentiation of coli-aerogenes group, 664

V factor in relation to growth of *H. influenzæ*, 790–793
Vaccination, 1888–1895
  complications of, 1894
Vaccine therapy. *See under individual diseases*
Vaccinia, 1884–1895. *See also* Smallpox *and* Chapter 55
  elementary bodies in, 953, 1887
  generalized, in man, 1894
    in rabbit, 1228
  presence of virus in circulating blood, 1233, 1889
Vagina, normal flora of, 1996
Variation of bacteria, 288–307. *See under individual species for variation in each*
